New from Pharmacia P-L Biochemicals

- DNase free
- RNase free
- Greater than 90% full length globin transcripts
- Efficient copying of input mRNA

AMV Reverse Transcriptase is the newest addition to our extensive line of enzymes for molecular biology. The enzyme is free of all contaminating nucleases and is tested to insure complete and efficient copying of mRNA.

With the introduction of Reverse Transcriptase, Pharmacia P-L Biochemicals now has the most complete line of products for cDNA cloning available. In addition to Reverse Transcriptase, we offer a full line of molecular biology enzymes including RNase H, DNA ligase, terminal transferase, DNA polymerases and restriction nucleases.

Ready-to-use vectors for cDNA cloning by either the Okayama-Berg or Heidecker-Messing cDNA cloning procedures are also available.

For Reverse Transcriptase and cDNA cloning, think of Pharmacia P-L Biochemicals!

- Forest succession
- Genetic determinants of smokers' cancer?
- Autumn Books

—GUIDE TO AUTHORS—

Authors should be aware of the diversity of *Nature's* readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, a return address).

Improve your 2-D electrophoresis results with 2-D Pharmalyte® 3-10

The latest in the extensive range of Pharmacia carrier ampholytes, 2-D Pharmalyte 3-10, brings new confidence to 2-D electrophoresis. Developed entirely within Pharmacia, this advanced grade of carrier ampholyte is the natural choice for all 2-D electrophoresis techniques entailing isoelectric focusing in the first dimension.

The exceptional properties of 2-D Pharmalyte 3-10 ensure

- Trouble-free focusing
- Unique batch to batch reproducibility
- Linear and stable pH gradients
- Reproducible pI determinations
- Product shelf life of over 5 years

For details of technical information and applications send for the free data sheet today or order 2-D Pharmalyte 3-10 directly from your local supplier.

Setting the standard...

[³H] Micro-scales

Easy, accurate way to quantify tritium distribution by autoradiography

Compare [³H] Micro-scales with your current quantification procedure for ease of use, speed, dependable uniformity and accuracy. Micro-scales from Amersham set the standard by which all others will be measured.

That's because each Micro-scale block consists of eight layers of tritiated polymer, arranged in order of increasing specific activity—from 3 to 110nCi/mg—and separated by inactive layers.

Using a standard microtome, the block can be sliced into hundreds of sections... each sized to fit on a standard microscope slide along with tissue sections. Then, when an autoradiogram is exposed and developed, tissue radioactivity levels can be calibrated directly against the Micro-scale.

Because hundreds of slices can be cut from each Micro-scale block, the cost per calibration is very low. And, potential applications extend to anyone currently performing [³H] autoradiography of cells, tissues or other substrates. For details, write or call for literature on [³H] Micro-scales. The new standard for autoradiography.

Nature in Poland

Readers wishing to subscribe to a weekly copy of *Nature* on behalf of a colleague in Poland (where hard currency is scarce) should send a cheque for £57 (or the equivalent in any currency), accompanied by their name and address and that of the proposed recipient, to the *Nature* office in London or New York (see addresses opposite page 87).

Next week in *Nature*:

- Part-sequence of extinct quagga gene
- Microtubule assembly
- Polyoma enhancer
- Insulin-like growth factor
- c-myc regulation of heat-shock proteins
- Immune-response maturation
- Archaeobacterial nitrogen fixation
- Slow neutrino puzzle
- Geodynamical iridium standard
- Autumn books — including reviews by Lewis Thomas, H.J. Eysenck, Lynton K. Caldwell, Christopher Longuet-Higgins, Nevill Mott, Philip H. Abelson, Jacquetta Hawkes and C.J.S. Clarke

—GUIDE TO AUTHORS—

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from *Nature* should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.

New from Pharmacia P-L Biochemicals

- DNase free
- RNase free
- Greater than 90% full length globin transcripts
- Efficient copying of input mRNA

AMV Reverse Transcriptase is the newest addition to our extensive line of enzymes for molecular biology. The enzyme is free of all contaminating nucleases and is tested to insure complete and efficient copying of mRNA.

With the introduction of Reverse Transcriptase, Pharmacia P-L Biochemicals now has the most complete line of products for cDNA cloning available. In addition to Reverse Transcriptase, we offer a full line of molecular biology enzymes including RNase H, DNA ligase, terminal transferase, DNA polymerases and restriction nucleases.

Ready-to-use vectors for cDNA cloning by either the Okayama-Berg or Heidecker-Messing cDNA cloning procedures are also available.

For Reverse Transcriptase and cDNA cloning, think of Pharmacia P-L Biochemicals!

The Greatest Revolution Since The Centrifuge

PERCOLL[®] **MIX AND SPIN**

An innovative density gradient medium which makes centrifugation simpler, quicker and gives much greater resolution than you ever thought was possible.

- Self-generating gradients in 30 minutes or less
- Isoosmotic throughout the gradient
- Non-toxic to cells and viruses
- Does not interfere with enzyme assays or quench radioactivity
- Low viscosity for rapid isopycnic or rate zonal separations
- Suitable for cells, viruses and subcellular particles
- Proven in hundreds of applications

ALL-WEATHER MAPPING OF SNOW COVER

Snow cover over central Asia, 11-15 March 1979, from NASA Scanning Multichannel Microwave Radiometer data (top) and US Defense Meteorological Satellite Program imagery (bottom). Blue denotes fully snow covered ground. Red, pink and yellow on the microwave image signify partially covered ground; grey, snow-free surfaces. Red on the visible image signifies partially covered ground; black snow-free surfaces and white, persistent cloud cover. (See page 434)

Look at the *NEW* Automatic Injector ACT-100 . . .

. . . because the Pharmacia Automatic Injector ACT-100 is a versatile, microprocessor controlled instrument designed to free you from the chore of repeated sample injection while your chromatographic separations run automatically.

The Automatic Injector ACT-100 is the state of the art in high performance biocompatible chromatography equipment designed specifically for the separation of biomolecules. Unlike any other injector, the Automatic Injector ACT-100 was designed,

from the beginning, to meet the demands of high performance separations of complex biomolecules. All wetted surfaces in the ACT-100 are of titanium and fluoroplastic. So the ACT-100 and FPLC System can combine to form a totally biocompatible system.

And, like the FPLC System, the ACT-100 is completely modular. Depending on your existing equipment, you can select the exact system configuration to give you a completely automated, biocompatible chromatography station.

. . . for automated biocompatible chromatography.

Complete automation with the Pharmacia Automatic Injector ACT-100 means

- Automatic analysis of up to 95 consecutive samples
- Accurate and reproducible results
- Unattended overnight runs, even with multi-dimensional systems
- Minimal operator time

The Pharmacia FPLC System and the Automatic Injector ACT-100 bring the full benefits of the latest technology to your standard methods. Together, they form the perfect biocompatible, high performance liquid chromatography system for the separation of labile biomolecules.

**FPLC from Pharmacia goes beyond HPLC
with biocompatibility.**

Nature classified Back pages

—GUIDE TO AUTHORS—

Authors should be aware of the diversity of *Nature's* readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.

Introducing a sophisticated

Behind every Smart Desk is a very smart decision-maker. Especially when the desk is equipped with a new IBM 3270 Personal Computer/GX.

This 3270 PC lets you create charts, graphs, 3-D technical diagrams and other high resolution graphics right in your office or lab. You can even view engineering designs created on other IBM graphics systems.

The graphics are created by downloading data from your company's main-frame computer or by running stand-alone. So, in either case, the host is free to go its way while you go yours. The results: faster response time and more cost-effective performance.

The 3270 PC/GX's 19-inch screen displays up to 16 colors. An optional "mouse" makes for fast, easy creation of graphics. An optional writing tablet lets your sketches appear right on the screen. There are even features that let you enlarge important details.

And, because this new computer is an IBM 3270 PC, you get a lot more than just pretty pictures.

It can display up to four different host sessions concurrently and run a full range of IBM Personal Computer applications. You also get two electronic notepads on screen for keeping track of important information.

IBM also has available a 14-inch model of the 3270 PC with advanced color graphics: the 3270 PC/G. Put yourself behind a 3270 PC/G or GX, and you'll

get the picture of how smart a Smart Desk can be.

To receive literature, call 1 800 IBM-2468, Ext. 731, or send in this coupon.

STANDING WAVES IN
A COMPOUND EYE

The long narrow photoreceptors in many insect compound eyes behave like waveguides, and light propagates along the receptor in the form of 'modes' or standing waves. In butterflies (here *Heteronympha erope*) these modes are imaged onto the corneal surface by a powerful lens found close to the tip of the photoreceptor (see page 561). (Photo: D.-E. Nilsson.)

New from Pharmacia P-L Biochemicals

- DNase free
- RNase free
- Greater than 90% full length globin transcripts
- Efficient copying of input mRNA

AMV Reverse Transcriptase is the newest addition to our extensive line of enzymes for molecular biology. The enzyme is free of all contaminating nucleases and is tested to insure complete and efficient copying of mRNA.

With the introduction of Reverse Transcriptase, Pharmacia P-L Biochemicals now has the most complete line of products for cDNA cloning available. In addition to Reverse Transcriptase, we offer a full line of molecular biology enzymes including RNase H, DNA ligase, terminal transferase, DNA polymerases and restriction nucleases.

Ready-to-use vectors for cDNA cloning by either the Okayama-Berg or Heidecker-Messing cDNA cloning procedures are also available.

For Reverse Transcriptase and cDNA cloning, think of Pharmacia P-L Biochemicals!

NATURE CLASSIFIED

Professional appointments — Research posts — Studentships — Fellowships — Conferences — Courses — Seminars — Symposia: Back pages

Next week in *Nature*:

- Gene enhancers repressed
- Synthetic antibodies
- Atrial natriuretic genes
- Lymphokine function
- Sea-urchin fertilization
- Ubiquitin
- Learning gibbon calling
- Distant saturnian rings
- Long-term solar periodicity
- Heavy cation dopants
- Reference books

—GUIDE TO AUTHORS—

Authors should be aware of the diversity of *Nature's* readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an abstract of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington (decisions being made only in London). Manuscripts should be typed (double spacing) on one side of the paper only. Three copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. References to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from *Nature* should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.

COVER

A representation of the hexameric rare earth dopant cluster in CaF_2 showing the minimum energy configuration after relaxation of the structure by computer simulation. Yellow spheres represent the six trivalent rare earth ions; red spheres, the interstitial, charge-compensating fluoride ions, and blue and white spheres, the lattice calcium and fluoride ions, respectively. See page 601.

REFERENCE BOOKS

This week's book review section is devoted to an eclectic choice of reference books published through the year, with emphasis on recently published animal encyclopaedias. On p.667 Anita Crafts-Lighty discusses a personal selection of the best biotechnology reference books published in 1984. Reviews begin on p.668, and an index to the books reviewed appears on p.679.

INTERNATIONAL WEEKLY JOURNAL OF SCIENCE

LIGHTNING-INDUCED ELECTRON PRECIPITATION

An energy-time spectrogram of lightning-induced electron precipitation from the Earth's radiation belts, as observed on the low-altitude S81-1 satellite. The colour scale indicates the electron flux, with red being most intense, and the vertical and horizontal axes represent energy and time, respectively. The three strong enhancements correlate with three lightning-generated whistler events (see page 740).

Ion exchange media from Pharmacia.

... proven and designed to meet your separation needs

More than twenty years ago, we at Pharmacia pioneered the first ion exchangers based on Sephadex®. Since then, their celebrated quality has ensured their transformation into the standard tool for ion exchange, attested by thousands, in laboratories worldwide.

Demands for macroporous ion exchangers of greater chemical and physical stability led us to develop our versatile range of Sepharose® ion exchangers, followed shortly after, by DEAE-Sephacel®, a pre-swollen, macroporous, cellulose-based medium.

The unsurpassed speed and precision of our recently introduced Sepharose® Fast Flow media, developed originally for industry, are equally valuable at the laboratory scale where

We realize that the choice depends upon your specific application and is governed, largely, by

- Complexity of separation
- Sample molecular weight
- Working pH
- Column or batch procedure
- Laboratory or industrial scale
- Economy

Let Pharmacia help you match the best ion exchanger to your applications.

European Missile Deployment

No defense decision has so strained the Western alliance and awakened the average citizen to the risks of nuclear destruction as the decision made by NATO in 1979 to install new nuclear missiles in Western Europe. Although the initial phase of the deployment has been successfully carried out, it has left in its wake an unforeseen series of painful and potentially lasting military and political consequences.

In a compelling 4-part series in *Science*, R. Jeffrey Smith describes the genesis of the deployment decision, the course of arms negotiations that followed, and the choices that lie ahead for NATO—choices that may influence the direction of future U.S. military expenditures as well as the potential risk of a superpower conflict. This reprint collection is available now.

Single copies \$2.00; twenty or more \$1.00 each. Orders must be prepaid.

Another monopoly on the block

This month's sale of the telephone company British Telecom will not bring competition but may net the government £4,000 million. The objectives are admirable but the methods are wrong.

JUST as there is no general answer to the question how long is a piece of string, so there is no easy way of telling what a national telephone network may be worth. That may be the most charitable excuse for the stratagems to which the British Government has gone, in the past few months, for selling off 51 per cent of the shares in its nationalized telecommunications industry, now trendily called British Telecom. Last week, after an advertising campaign intended to interest men in the street in becoming shareholders (and which must have done more for general business education than decades of formal education), British Telecom and its merchant bank last week published the draft of the prospectus on which its shares will be sold on 28 November. The only missing ingredients in the prospectus are the price at which shares will be offered for sale, and the precise proportions that will be set aside for employees of the company, investors overseas and so on. Everybody is a little agog that on this one day, anything up to £4,000 million may change hands (although only 40 per cent of it will be payable on the nail).

While there is every reason to applaud the government's chief objective, that of introducing some of the self-balancing discipline of the marketplace into the regulation of a gigantic industry, suspicion must persist about its secondary objectives (balancing its budget by selling off its capital assets) and there are grave doubts about its methods.

The laudable primary objective is now quite widely shared. Only this year, the US telephone network, AT&T, has been broken up into a number of smaller units, with geographically restricted monopoly rights. The Japanese Government is dicker with similar schemes. Everywhere, monopolistic telecommunications have become technically backward (or less technically advanced than they should be) and commercially slothful. Two quite separate tendencies have made the telephone monopolies indefensible. First, as experience in the United States has shown, allowing small companies to offer "value added services" by renting trunk circuits from the monopoly and selling on their use can benefit both the entrepreneurs and their customers. (The monopolies protest that these parasitic middlemen are merely skimming the cream off their legitimate business, to which the answer is that they should design their tariffs more intelligently.) Second, technology has often left the monopolies standing almost still and, in the past decade, with satellite communications in particular, has begun to raise the question whether telephone systems need now be the monopolies that seemed inevitable in the days of Alexander Bell. The British Government deserves some praise for recognizing that the time has come for change.

The British solution to the problem of the monopoly is at best half-hearted. There are three innovations. First, half of the telecommunications will in future be owned by private investors, not the government. The chief practical consequence will be that British Telecom will in future be able to raise capital from private sources without embarrassing the Treasury by inflating what is called the Public Sector Borrowing Requirement (which will assist technical innovation). Especially because the government promised, in last week's prospectus, not to vote its shares in ordinary circumstances, this change by itself is not a safeguard for the users of the network but, if anything, a device whereby the new owners can decide what profit they should be making. To guard

against exploitation, there are two safeguards — a regulatory office (called Oftel) with powers to rule on complaints of unfair competition which has yet to show its teeth (but they look sharp) and a requirement imposed by the government that domestic telephone tariffs should not in the next five years increase by more than two per cent less than the inflation rate (which is meaningless, because the new corporation is almost certain to wish to finance a greater share of its development by borrowing than in the past). Third, there is a simulacrum of independent competition, a quite separate telecommunications network called Mercury.

The best that can be hoped for, in these novel circumstances, is that the competition will prosper. The worst possible outcome is unthinkable, for the political trouble there would be if Mercury should be in danger of collapse would have the government and the Bank of England at its side in a flash. (Perhaps the moral of last week's prospectus is to invest in Mercury, not British Telecom.) Meanwhile, the British Telecom prospectus cheekily reminds potential investors that the restriction of its tariffs laid down by the government will apply to only 45 per cent of its business. (To be fair, the rest includes international telephone traffic, where competition is likely in due course to be fierce, and the sale of equipment, where it is already cutthroat.)

Meanwhile, the question remains how much the business may be worth. The government's embarrassment is that there is no objective way of putting a value to its worth. The value of the income stream from a monopoly enterprise is not necessarily related to anything but the decisions taken by individuals as to what the profit should be. The value of the network's assets, calculated from the cost of providing them in the first place but abated by depreciation, may conceal as assets equipment so inefficient that, in a competitive world, it would be thrown away. One of the curious anomalies in last week's prospectus is the brief statement on depreciation policy, disclosing that British Telecom reckons on an average life of between 6 and 20 years for its old Strowger electromechanical equipment, but a uniform ten years for new digital equipment.

The sale now arranged has inevitably an air of unreality. Ultimately, what will matter is how much people are prepared to pay for half of British Telecom. The best way to have found out would have been to put the shares on sale in dribs and drabs, on exactly the pattern in which the government itself sells government stock. The way in which things have been arranged, however, is certain to cause embarrassment. If the shares on offer are not taken up, the government will be laughed at. If on the other hand, the shares sell like hot cakes, it will be accused of having given away a public asset. It has only itself to blame. □

Research competition

British universities had better become knowledgeable about their research.

THOSE who think that the long agony of the British academic research enterprise must be coming to an end had better think again. That is the simple lesson to be drawn from last week's announcement by the Science and Engineering Research Council that it is now embarked on finding fields of research or important

research institutions, from which it can withdraw support. The plan is to find things to drop by early next year, and no later than April. Meanwhile researchers who may with gratitude have been allowed to retire from academic committees brooding on the future of their universities will now find themselves sucked up into another round of endless meetings, this time about research support. Before the dust has settled, there will be a great deal to be said on the important and daunting questions underlying the new round of enquiries.

In the past few years, the much-vaunted British system for supporting academic institutions, the dual-support system, has come to resemble a pair of millstones between which the research enterprise is being ground. Theoretically of course, there should now be no immediate problem. The contraction of the universities has come to an end, the British Government has been hinting that henceforth "level funding" will apply, while the government has in strict monetary terms kept its prime minister's promise (in 1980) that the civil research budget would be "protected". The snag is that constant budgets for the universities in present circumstances imply a steady drain of 0.5 per cent a year in real resources, while the constant research budget (spent through the research councils) has now to cover a greater range of activities, including payment of pensions to people whose services are no longer required. No wonder that the University Grants Committee is threatening (but some will say promising) greater selectivity in support of particular universities, and that the research councils are having to draw in their horns.

With this in prospect, any sensible British university should take a few simple protective steps. First, it should set up a research committee to attempt to decide on its priorities. The inescapable reason for doing this is simply that the universities were told to do just this two years ago, in the report of an investigation in whose existence the grants committee had a hand. But there is also a chance that such an arrangement would give the universities a capacity which they at present lack for knowing and then for understanding the range of research that their academics at present conduct. (In passing, it might be acknowledged that part of the trouble underlying British academic research in recent decades has been the indifference of universities to their own achievements.) And there is no doubt that such an understanding will be essential eighteen months from now, when the men from the University Grants Committee set out with their scalpels.

To be safe, however, universities should be careful to distinguish between academic research and the now fast-growing volume of industrial contract research carried out within universities (the once watchful eyes of the revenue authorities temporarily blinkered by the climate of the times). To say this is not to echo old-fashioned notions about the relative merits, intellectual and otherwise, of the two kinds of activities but is simply to say that managing academic and industrial research are different activities, often calling for different people. And while there is every sign that the British Government (and thus, to some extent, the grants committee) will applaud those institutions that earn a large proportion of their income from contracts, there is as yet no sign that the grants committee will relax its traditional standards of scholarship when choosing between the sheep and the goats. Moreover, that process cannot now be long delayed.

For the institutions responsible for managing the impending change, the grants committee and the research councils, the benefits of acting quickly are now overwhelming. The grants committee wants to concentrate research at a smaller number of universities within a system accommodating as many students as at present, while the research councils must somehow shed a large proportion of their fixed overhead cost, that represented by their commitment to research institutes and the people there employed. In an ideal world, they would put their heads together and recognize that their problems would more easily be solved in concert than separately. The only evil consequence would be that the goats (or is it the sheep?) among the universities would more quickly know where they stand — and that a greater proportion of them would be wrongly classified. Such a recognition of common sense may be the next threat to the universities.

Animal crackers

Using the cloak of animal rightists' groups to persecute people is wrong.

IN the pathology of personal vindictiveness, the way in which an unidentified resident of Pennsylvania has apparently set out to damage Dr Robert Weinberg, a professor at the Whitehead Institute at Massachusetts Institute of Technology, breaks alarming new ground. Last month, researchers in Britain as well as the United States were circulated with an anonymous notice, purportedly from an organization called the Animal Liberation Front, which uttered unspecified threats at those in cancer research who use animals in their experiments, but which singled out Dr Weinberg for having presented at *Nature's* September conference in Boston a paper supposedly encouraging painful animal experiments. The title of the paper was given as "Neoplasms as uncontrolled regenerative hyperplasia", which will have seemed a little odd to the many who know Dr Weinberg's work. To suggest that his activities entail more than the most marginal dependence on laboratory animals is, of course, laughable, which is the spirit in which the incident was reported a few weeks ago (*Nature* 4 October, p.401).

Since then, the plot has thickened. Whoever circulated the anonymous notice seems also to have been circulating scientific papers supposedly written by Weinberg. One curious feature of these documents is that they appear not to involve the kinds of experiments with animals that would send the animal welfare people into a frenzy. Weinberg has discovered that the fake paper he was said to have read at the *Nature* conference (at which, in reality, he gave a sober review of the recent molecular biology of oncogenes) had actually been mailed to him, under different authorship, several months earlier (when it had been filed together with other crank cancer theories). More mystifying is a letter, apparently widely circulated, that purports to be a manuscript submitted to the *New England Journal of Medicine* which puts forward a proposal for the use of steroid hormones in the treatment of breast cancer. An accompanying note says that the editors of the *Journal* would be grateful for comment. Again, there is no mention of the use of experimental animals.

There are several lessons to be learned from this curious chain of events, not the least of which is the discovery of how easily a researcher's attention may be distracted by malevolent and apparently pointless activity. It is, however, intolerable that productive people should be thus preoccupied. The best way to deal with nuisance mail of this kind is to tell the police, urge them to investigate and to forget about it all. That, unfortunately, is easier said than done, as will be verified by anyone who has personal experience of knowing there is somebody nursing some kind of hate. The calculation that the anonymous watcher is probably psychiatrically disabled is little comfort. Since Weinberg has not been the only target of the anonymous nuisance-monger's attention, it may be worthwhile that others affected should communicate with him or with *Nature*.

Second, while there is no serious danger that a well-established reputation could be shaken by the circulation of nonsensical papers, there is every chance that people's professional opinions could be altered in subtle ways by the circulation of, say, preprints masquerading as serious works. People should be on their guard against such dangers, unlikely though they may appear.

The use of the slogan "Animal Liberation Front" on some of the communications from Pennsylvania points to another hazard — the danger that ill-considered actions by people who should know better will provide a cloak beneath which unwelcome allies may have their fling. Of necessity, because it is a banner for often illegal activities, the Animal Liberation Front cannot be a formal organization, with a constitution and a membership list. The result is that anybody can join, gaining attention for private causes from the publicity that has been engendered by those whose interest is to break into laboratories and animal houses. The hazard is one of those attending the activities of all terrorist organizations, however well-intentioned.

US space research

Space station threat to science spending

AN enormous share of the US National Aeronautics and Space Administration (NASA)'s space science budget may wind up supporting the space station, according to some initial assessments by scientists advising the agency. Peter Banks of Stanford University, chairman of a panel looking into scientific uses of the station, said last week that \$400–600 million a year might be spent by "code E" — NASA speak for its science budget — on space station projects. The NASA science budget is now \$1,404 million, which goes to support both basic research, mainly at universities, and such major projects as the space telescope and the Venus Radar Mapper mission.

The space station programme, which received official presidential approval last January, will not be able to purchase scientific instruments or support research and analysis activities with the \$8,000 million tentatively approved for the project. All of these expenses with presumably be borne by code E. NASA officials say that \$8,000 million will buy a basic manned module, two accompanying unmanned platforms, and an orbiting manoeuvrable vehicle to transfer payloads from the station orbit to higher orbits.

Some scientists, particularly those interested in Earth observation experiments, say that a single polar platform cannot be large or flexible enough to meet their needs, which means that the potential cost savings from sharing power supplies and communications equipment on the space station platforms will not be realized by the science budget. NASA appears to be resisting suggestions that a flotilla of small platforms be built in place of the large platform.

NASA has just sent out its request for

proposals for initial design studies of the station, and the specifications include the two large platforms. Contractors for the initial design work will be chosen on 1 April next year. (John Hodge of the space station programme told Banks's committee this summer that the large platforms provided a more "unified" approach to the programme and would be well suited for commercial projects, such as manufacturing in space.)

Despite such concern, space scientists are reluctant to criticize NASA's space station plans. The frequently heard argument is that, because the space station is going to be built in any event, the best thing scientists can now do is to offer their full support. In that way, they can hope to influence some design details to ensure that some good science can be carried out.

Burton Edelson, director of the Office of Space Science and Applications, told the Space and Earth Sciences Advisory Committee last week that, because his office had been "supportive" of the space station over the years, it had already been able to make the project "more suitable" for science. He said there would not have been unmanned platforms at all if it were not for his office's advocacy.

At the same time, some say that there are great political pressures on the NASA science programmes to make use of the space station, which is seen by many as long on engineering and short on purpose. The same reservations were expressed, to a lesser degree, about the role of science in the shuttle programme. The Office of Space Science and Applications is spending 13 per cent of its current budget on shuttle projects.

The Banks committee, significantly, was not asked to decide whether scientific

activities could better be carried on the station, but only what activities could be carried out on it. It seems agreed that the space station opens up some new possibilities but most of the experiments listed by Banks's committee, and by the Space Science Board in a separate study, could clearly be done as well if not better without the station.

Some relief for the science budget may come from abroad. NASA administrator James Beggs has been pushing hard for Japanese and European contributions to the cost, to the tune of \$1,000 million and \$2,000 million respectively. There is some talk of the foreign contributions going for a second polar platform.

Stephen Budiansky

ESR to Grenoble in Franco-German deal

Paris

OFFICIALS representing Hubert Curien and Heinz Riesenhuber, the French and German science ministers, last week had to answer for the Franco-German decision to site the European Synchrotron Radiation Source (ESRS) at Grenoble.

On Friday in Brussels, they met their opposite numbers from the smaller European states under the auspices of the European Science Foundation (ESF) "progress committee" which — according at least to Denmark and Italy — had been gathering and evaluating site proposals. Instead, the committee was faced with a decision by France and Germany that ESRS should be built in Grenoble.

In fact, the first notice other governments had of the "decision" — except for press reports — came in a joint letter from Curien and Riesenhuber only on Tuesday last week, too late for official reactions by Friday. What may now emerge is an agreement between France, Germany, Britain and Italy to which the smaller states, notably those of Scandinavia, might adhere in a separate consortium. But Denmark, clearly the most hurt is unwilling to participate. The Netherlands is also playing cool.

Meanwhile, Britain, which France and Germany dearly want as a partner, while strongly backing the Grenoble site, has no money to offer, and may enter only with observer status "or something between that and full participation". The French certainly are not keen to see ESRS start up as a purely Franco-German institute, as the Institut Laue-Langevin was before 1967.

And why did France and Germany (and in effect the United Kingdom) ignore the ESF progress committee? Because it had too low a political level, say French sources, and would have been unable to trade one facility for another. This, finally, is what France and Germany did with ESRS and the trans-sonic wind tunnel, now to be built at Cologne. Robert Walgate

Europe in space

Italy treads Columbus path

US pleas for European collaboration in the planned space station have won hearts and minds in Italy. The Italian minister of research, Mr Luigi Granelli, was in London last Friday to persuade the faint-hearts of the British Government that they should contribute some £40–50 million a year from 1986. For Granelli, Europe's only future lies in space. "We've fallen behind in electronics and in biotechnology; we just can't afford to fall behind in space as well." His own government appears to agree. But Britain is still counting its pennies.

Mr Granelli's enthusiasm may yet work in sceptical London the magic it has worked in Rome. Earlier this year, seeking an increase in the budget of the "national space plan", Granelli told his cabinet colleagues that they should either cut the annual 50,000 million lira (£20 million) plan to nothing, or increase it four-fold. "It would have been a waste to continue spending just the 50,000 million lira" he said last week. The Italian cabinet seems to have agreed, to have pulled down their visors and taken a walk in space with Mr Granelli. From this summer, Italian space spending has risen to 150,000 million lira, and will reach 200,000 million lira next year (see box). Italy's contribution to the European Space Agency (ESA), at present 120,000 million lira, comes on top.

Safety in numbers

THE increased Italian space budget is mostly to be spent on technology, but X-ray astronomers may just benefit. The package includes approval for a "phase-B" detailed design of an X-ray satellite (SAX), Italy's first, due for launch at the end of the decade. Italian astronomers have been seeking outside collaborators on instruments for SAX which already, according to some observers, has too many small instruments incorporated to satisfy this or that hungry group of Italian astronomers.

International collaboration could stretch SAX further. Discussions are now at a critical stage with Dutch high-energy astronomers, but Britain and West Germany have been occupied with their collaboration in the German-designed ROSAT. Now, however, Italy may face a problem with the Dutch Government, which has set its face against further satellites after last year's infrared satellite IRAS.

Apart from SAX, other items on the Italian agenda include ITALSAT (a telecommunications satellite) IRIS (a Space Shuttle upper-stage that would put SAX in orbit), TSS (a tethered "satellite" to hang in the atmosphere 100 km beneath the Shuttle) and LAGEOS, a geodesy satellite (also launched by an IRIS-Shuttle combination).

Robert Walgate

Granelli urged the same argument last week on British industry and information technology minister Geoffrey Pattie. Granelli is convening the first ministerial meeting of ESA since 1977 in Rome next January to plan Europe's response to the US invitation. He hopes that British ministers will not be dragging their feet.

Europe needs "coherence" and "a vision" in the face of the National Aeronautics and Space Administration (NASA)'s plan to begin detailed design of the space station (phase B) on 1 April, 1985, and to start construction in January 1986. A series of bilateral arrangements with NASA would be dangerous, he believes, so he seeks a 70 per cent increase in the ESA budget in the period 1986–91.

The Italian vision, shared by West Germany (see *Nature* 25 October, p.696) is that of Columbus, and adjunct to the space station consisting of a manned laboratory (developed from Spacelab), an experiment platform and a control module. But Granelli, statesmanlike, says he is more interested in principles than details. There are as many technical proposals for collaboration as there are space technicians in Europe, he admits. Whether or not Europe builds Columbus matters less than that the old continent should safeguard "our standing and negotiating power with the United States".

In Britain, the issue appears to be whether Europe should plan a truly independent manned capability in space (as seems to be the view in Italy, West Germany and France), almost without counting the cost, or whether the approach should be more gentle. Nevertheless, it is stressed in London that "Britain wants to do something European". There are fears that mainland Europe is beginning to write off Britain as a potential partner. Collaboration in the space station may be a test.

The effect of all this on the space science programme is cloudy. Granelli said last week that he did not know what would happen to the recommendation that ESA's mandatory space science programme should increase by 40 per cent by 1990, mostly for astronomy.

In Britain, cabinet sources suggest that cash for any space station collaboration should come out of "a political pocket", leaving existing space sciences unaffected, but Granelli is not so sure. "When you talk of science, you must think beyond the existing community of space users." Granelli was thinking of "science in zero-gravity" — materials processing and so on. But he added that Earth scientists and astronomers now using space through ESA should not "in principle" suffer, although "someone has to make a choice in the end." So something may be sacrificed on the altar of the space station.

Anglo-French cooperation

New guise plea

FRANCE and Britain should set up a joint foundation with the aim of linking universities and industry, the French President, François Mitterrand, told the British Parliament last week. A new idea? No. But each time it pops up it takes a slightly different shape, and each time Britain knocks it down again.

The idea first surfaced in Edinburgh two years ago, during a meeting of the largely commercial Anglo-French Council, when the research director of the French oil and chemicals company Elf-Aquitaine proposed a joint research and development planning agency. This was to be heavily weighted towards industry, and was to devise more projects like the European Airbus.

That plan died until Robert Chabbal, a director at the ministry of research in Paris, transformed it into a proposal for a series of bilateral science and technology seminars. These have taken place — but between France and Sweden, and France and West Germany, rather than with Britain. The British view is that France has gained more than Sweden or West Germany from the meetings so far.

Meanwhile, the science counsellor at the French Embassy in London has been trying to convince his British colleagues that some kind of collaborative structure should be established between Britain and France, but without much success. The French view is that collaborations move best beneath a well-defined governmental "umbrella agreement". The anarchic British, however, say there are already plenty of routes for collaboration, and therefore no need for new structures.

President Mitterrand's intervention may have been stimulated by the suggestion by British science minister Peter Brooke, at the Council of Europe last month, that Europe should establish an international science academy. The French consider that this may be a sign of enlightenment in Britain, perhaps even a basis for their own idea of a science-industry forum.

The British are still reluctant, however, and suspicious that France merely wishes to tap British invention. They may be right. M. Guy Denielou, president of France's only technological university (Compiègne) said last week that he fully approved of an institution such as Mitterrand had proposed.

"Of course, I would hope to be a customer" he said. "British research is too big for British industry... All your ideas get taken up in America or Japan." It would be a good thing, said Denielou, if British science could feed some ideas into French industry as well. The same thing could also happen in reverse, he said. But the suspicious feeling in Britain, rightly or wrongly, is that the traffic would work out

Chinese nuclear power

Japan sets sights on business

Tokyo

THE chief obstacle to an atomic energy cooperation pact between China and Japan, the unwillingness of China to permit verification of non-military uses, seems likely to be removed in the coming weeks. China is now apparently prepared to allow some sort of inspection of nuclear plants supplied by Japan to be carried out under the supervision of the International Atomic Energy Agency (IAEA).

The exact form that inspection will take is not, however, clear. On the Japanese side, Michiyuki Isurugi, minister of state for the Science and Technology Agency, was willing only to say that Japan had received a "new proposal" in response to its wish, repeated over four rounds of talks, that China accept supervision by IAEA or provide other concrete means of guaranteeing peaceful use of atomic energy facilities. Isurugi did, however, express confidence that he would be able to travel to Beijing in the next few weeks to sign a pact. The Chinese side seems to have been rather more forthcoming, according to an article in the *Asahi Shimbun* claiming that officials in Beijing had stated they were now willing to allow IAEA inspection.

Earlier this year, Japan had received promises that China would allow "goodwill" visits of Japanese experts to Japanese-built plants in China. This was enough for Mitsubishi to go ahead, with government encouragement, and win a ¥1,500 million (\$6.3 million) contract, against strong French and West German competition, for pressure vessels (using US Westinghouse technology) for one of China's first nuclear reactors. But lack of a full cooperation agreement was thought by the nuclear industry to hinder its competition with the French, West German and British companies that have joined the rush to build nuclear power stations in China.

Much is at stake, for China is the last major nation without any nuclear power generating facilities and has committed itself to installing 10,000 megawatts of capacity — a minimum of ten reactors — by 2000. US companies, whose home market has dried up, should be the strongest in the field, but are for the time being sitting on the sidelines, waiting for the US-China nuclear cooperation agreement announced last April to be approved by (or at least submitted to) Congress (see *Nature* 309, 657; 1984). France, Italy and Brazil have already signed nuclear agreements with China — although none is so extensive as that signed by West Germany — and the Soviet Union has also indicated its willingness to sell reactors to China, apparently without assurances on strictly non-military use.

Meanwhile, construction has begun in China on two nuclear plants, one of 300 megawatts at Qinshan near Shanghai

which will use a Chinese-designed pressurized water reactor (PWR) with pressure vessels supplied by Mitsubishi, and the other with two 900 MW PWRs near Canton, which will supply part of its power to (and be partially financed by) Hong Kong. Final contracts for the second reactor have not yet been awarded but discussion has reached an advanced stage with Framatome of France for the reactors and the General Electric Company of the United Kingdom for the turbines.

Two more power stations are in the offing: one near Shanghai and a second in the northern Liaoning province. If US activity remains frozen, contracts for one of these could go to West Germany, to judge from Chancellor Kohl's optimism during his recent visit to Beijing.

When the US presidential election is over, though, the United States-China atomic energy accord is expected to be given high priority. If US companies get

back into the field, competition will be much more intense. But Japanese manufacturers still fancy their chances, because they have the best operating efficiency record in the world and believe China will go for reliability.

US commentators, on the other hand, have quoted Chinese officials as saying that they want to learn from the "teacher, not the student!" — virtually all of Japan's nuclear technology is derived from US designs. China is, however, almost certain to distribute its contracts among the advanced nations both to encourage cut-throat competition and to ensure that it can always ride out a sudden worsening of relations with one or more of its suppliers. Nor can the apparent willingness of China to allow inspection of Japanese plants be regarded as a signal that similar concessions will soon be made to the United States. Last April, when the possibility of "goodwill" inspection came up, the Chinese said they were taking into account Japan's unique position as the only country in the world to have been hit by nuclear weapons.

Alun Anderson

Atmospheric chemistry

Preparing for crises ahead

Washington

CITING "essential unanswered questions" about changes in the Earth's atmosphere, a US National Research Council panel has proposed a long-term international study of tropospheric chemistry, to be led by the United States. At a public meeting here, panel members agreed on the need to understand basic atmospheric processes in order to provide sound advice to policymakers and to avoid "crisis responses" to environmental problems. The panel's chairman, Robert Duce of the University of Rhode Island, said the proposed "Global Tropospheric Chemistry Program" could by the end of the century allow the impact of atmospheric changes to be anticipated.

Several panel members conveyed a sense of urgency about the unknown effect of documented atmospheric changes. Ralph Cicerone, the panel's vice chairman, said it was "shocking" how little is understood about cycling of atmospheric constituents. Dr Jerry Mahlman of the National Oceanic and Atmospheric Administration, an independent supporter of the programme, drew attention to increasing atmospheric levels of trace gases, especially methane, which could have an effect on temperature "equal to or greater than" carbon dioxide and which "can be expected to cause a 20°C cooling of the stratosphere within two or three human lifespans". Mahlman said nobody knows why methane levels are rising and that "we ought to find out".

The research council panel had been convened at the request of the National Science Foundation and the National Aeronautics and Space Administration.

The proposed study was generally welcomed, but there were some reservations about the apparent dominance of a supposedly international programme by the United States: the Global Tropospheric Chemistry Program is seen as a large component of the International Geosphere Biosphere Program recently approved in principle by the International Council of Scientific Unions (see *Nature* 4 October, p.402). Henning Rodhe, professor of chemical meteorology at the University of Stockholm, pleaded for a genuine international effort and reminded the largely US audience that "there is some atmospheric chemistry outside the United States".

The new programme would in its early stages concentrate on developing new instrumentation and classifying ecological habitats by their effect on the troposphere. Later research would focus on biological sources of tropospheric constituents, global distribution of trace gases, studies of photochemistry and investigations of removal processes. New global models would incorporate scavenging and chemical reactions in cloud droplets.

There has so far been no serious attempt at costing, but, according to one "very crude" estimate, the \$10-20 million spent annually on tropospheric chemistry in the United States would need to be doubled to get the programme started. Detailed proposals are to be drawn up at a series of workshops organized by Dr Cicerone. But the panel acknowledged the difficulty of persuading Congress to support a programme unlikely to produce useful results within 10 years.

Tim Beardsley

Cancer mortality

US half-rate goal in dispute

Washington

THE National Cancer Institute (NCI) continues to defend its "achievable" goal of halving US age-adjusted cancer mortality by the year 2000, first announced (to great dramatic effect) before the US Senate appropriations committee in April this year. But NCI has yet to make public any detailed justification for this claim, and its feasibility has been questioned. NCI plans to publish a full description of its year 2000 programme in 2 or 3 months, after review by the National Cancer Advisory Board.

Since 30 per cent of the 440,000 deaths from cancer each year in the United States are attributable to cigarette smoking, all agree that curtailing smoking is crucial. NCI's provisional estimate is that it should be able to halve lung cancer mortality by 2000 by preventive measures alone. But there are doubts whether NCI can achieve the 50 per cent reduction in smoking over the ten years to 1990 needed for this target.

As a government agency, NCI is prevented from lobbying for what is known to be one effective means of reducing smoking: higher taxes on cigarettes. NCI's weakness on this score was underlined in the summer, when Congress voted to lower cigarette taxes as part of a compromise that included strengthening the health warning on cigarette packets. For the same reason, NCI cannot take a position on, for example, banning cigarette advertising or restricting smoking in public places. And NCI's own advertising efforts are limited to free "public service" air time donated by radio and television stations and pamphlets distributed in physicians' waiting rooms. The emphasis is on helping only those who want to stop smoking, rather than encouraging confirmed smokers to reform.

Even if smoking could be halved by 1990, success in halving lung cancer by the end of the century would be far from assured. While smoking appears still to be decreasing among males, there are signs that it is increasing among females, and such reductions in smoking as there have been in recent years have been restricted to the higher socioeconomic classes. In order to reach the target, the NCI programme would have to be effective among the older/heavier smokers who are most at risk but the hardest to convert, according to Dr John Higginson of Universities Associated for Research and Education in Pathology. Dr Lewis Kuller, director of the department of epidemiology at the University of Pittsburgh, goes further, saying that the year 2000 goal on lung cancer will be achievable only if a chemopreventative agent is discovered for treatment of those who have stopped smoking.

The target is defended by Dr Joseph Cullen of NCI. The institute is about to embark on large-scale intervention trials

that will include 10 million subjects over 5 years, designed the better to define how to persuade people to stop smoking. There will be a special programme for high-risk groups, and physicians will be trained in anti-smoking counselling. Cullen predicts that NCI will extend its influence with policy-makers and the media, and that the continuing shift in public attitudes will be helped by, for example, boycotts against magazines that carry cigarette advertising. Cullen will not be drawn on how NCI will get around the statutory limits on its authority except to say that more federal and state funds will have to be used.

Smoking aside, NCI plans to achieve a further 15 per cent reduction in cancer mortality by the year 2000 by ensuring full public access to state-of-the-art treatment. Dr Peter Greenwald, director of NCI's division of cancer prevention and control, says this target makes no allowance for advances in treatment yet to be discovered or for earlier detection, but that it is based on treatments now at the stage of clinical trials. On top of the reduction due to improved access, Greenwald anticipates another 15 per cent reduction due to improved treatment of micrometastases; he points to experimental treatments using monoclonal antibodies targeted at specific oncogene products. While acknowledging that the figures might be disputed by a conservative statistician, Greenwald stresses the importance of having goals.

Others doubt whether these dramatic predictions can be defended. While more widespread screening programmes could markedly reduce breast cancer mortality (possibly by up to 30 per cent), and perhaps cervical cancer also, the other major killers seem stubbornly resistant to improved treatment. Kuller says he "would have difficulty being convinced" that these improvements are in prospect without further major advances in early detection. Tests for cancers of the gastrointestinal tract, for example, are still much needed.

Perhaps the most controversial element of NCI's year 2000 plan is the goal of reducing mortality by 5 per cent by changing eating habits. While inter-population comparisons indicate that up to 35 per cent of cancers may be caused by dietary factors, the precise components involved are not known. Despite the small number of studies of fibre intake and cancer, NCI's director, Dr Vincent DeVita, told the Senate Appropriations Committee in April that a doubling of fibre intake could reduce colon cancer by 30 per cent by the year 2000. NCI also now believes that a reducing fat consumption will help.

Others are not so sure: Kuller says the 5 per cent target "could be wishful thinking". In 1982, the National Academy of Sciences concluded that it was impossible to quantify the likely effect on

cancer incidence of dietary changes. Higginson believes the effect of diet on cancer incidence in adults has been exaggerated, and points out that the reductions in fat consumption seen in recent years, which have had a marked effect on heart disease, have so far failed to have the effect on cancer incidence that would be expected according to the simple dietary hypotheses, thus making the overall NCI target even less realistic.

Tim Beardsley

European environment

Hopes to reform farming

Brussels

THE European Community may be about to mount a vast new programme of research and development in agrochemicals. That, at least, is what will happen if the commissioner for environment and internal market affairs, Mr Karl-Heinz Narjes, gets his way. At a conference in Dublin two weeks ago, Mr Narjes argued that pesticides and fertilizers have had an undesirable effect on the environment, and that the time has now come to encourage technical innovation to yield more selective but less persistent pesticides.

The environment commissioner has been trying for some time to persuade his colleagues in the commission that environment policies should be integrated with others, and with agricultural policy in particular. Formally, this principle is written into the current action plan on the environment. Now there are signs that the member states are coming round to Mr Narjes's way of thinking.

Mr Narjes is not anti-farmer. Instead, his aim is that agriculture should continue to profit from the use of chemicals without putting an intolerable burden on the environment. In Dublin, he was pleading for more work on the toxicology of pesticides, allowance for regional and national differences of cultivation techniques and a training programme for farmers.

Within the Community, the Dutch Government has already advocated the use of European Community funds to protect the environment linked to farming in less-favoured areas. Meanwhile, the United Kingdom, backed by Ireland, has been urging that Community agricultural funds should be made available to farmers for "environmentally friendly actions".

The outlook for Community regulation of agricultural pollution seems less bright, however. Member states have been unable to agree on a list of acceptable pesticides since 1976, while proposals for maximum permitted levels of pesticides in foodstuffs have been gathering dust since 1981. Mr Narjes seems bent on circumventing the regulatory log-jam by tackling the problem at source.

Anna Lubinska

Soviet meteorology

Bolts from out of the blue

Up to 25 per cent of recorded weather information fails to reach the Soviet Union's Hydrometeorological Scientific Research Centre, the new director, Aleksandr Vasil'ev, has told an *Izvestiya* correspondent. The interview is also the first indication that Vasil'ev had been promoted from his former post as deputy, thus generating speculation that his predecessor, Dr Mikhail Petrosyants, had been dismissed for failing to forecast the hurricane which caused widespread devastation in the Russian Federal Republic on 9 June.

The storm, apparently caused by a warm dry airstream from the eastern Mediterranean meeting a cold airstream from the Barents Sea, has cost the Soviet Union upwards of 120 million rubles (\$150 million) in restoration work, compensation and insurance. Devastation of houses and "production facilities" is reported from Ivanovo, Gor'kii, Kalinin, Kostroma and Yaroslavl as well as in the Chuvash republic, with an unspecified number of deaths. A special resolution of the party central committee and the Council of Ministers to make good the damage done by "a natural calamity" was passed in mid-July.

The Ivanovo hurricane was followed almost immediately by three further meteorological calamities — extensive flooding in the Baikal area in mid-June, a hurricane in the Volynia district in Western Ukraine in mid-July and flooding in the Amur basin "complicated by Typhoon Holly" in late August. But in these cases, although there was considerable damage to agriculture and production schedules, some warning seems to have been given. In the case of Ivanovo, however, there was apparently no warning.

Reliable weather forecasting is particularly important to the Soviet planned agriculture, where the logistics of sowing and harvesting are determined regionally. Moreover, Soviet meteorologists still have to live down the memory of last autumn, when the unexpected onset of severe weather left more than 40 ships of the Arctic mercantile fleet stuck in the ice.

In the event, the new icebreaker *Leonid Brezhnev* extricated the vessels. The Soviet press at the time stressed the valuable lessons learned for future Arctic navigation, which may be why the northern navigation season has been ended several weeks earlier this year. But *Pravda* also noted a year ago that Arctic weather was not by itself "guilty" of causing the emergency, and that all those responsible for the ships' presence in the ice so late in the season should share the blame. Coming only a few months later, the Ivanovo hurricane may well have made it necessary for the meteorological service to offer a scapegoat. And, at 65, Petrosyants is

But is Vasil'ev justified in blaming the problem on poor information flow? The question is pressing because of the new drive to extend the use of "improved" land, which has to be made fit for agriculture by either irrigation or drainage. Last week's central committee plenum admitted that all is not well with the much publicized food programme, launched by Leonid Brezhnev only in 1982, and "further measures" were urged by Mr Chernenko including a major extension of irrigation and the bringing in of virgin land, in Soviet Central Asia. River diversion projects, allowed to lapse during the Andropov era, seem on the way back. Yet even the most optimistic planners admit that such schemes can only yield the projected harvests if every drop of irrigation water is carefully husbanded. Failures in weather forecasting could have serious results.

The Soviet meteorological service

appears to have the technical means. It maintains a union-wide network of weather-watch stations, including "out-posts" such as that on Franz Josef Land, and a fleet of weather ships, which not only participate in forecasting programmes but also attempt to correlate Soviet weather conditions with such factors as the change of sea temperature in the northern Pacific. As early as 1970, experiments were under way with networks of automatic recording stations which would feed data automatically into a computer.

Reliable weather forecasting is also one of the main justifications for the Soviet space programme, while the export of meteorological equipment and the training of operators form an important part of Soviet aid programmes to developing countries. Vasil'ev's suggestion, that it is not the information gathering but the information transmission system which is at fault, is one to which the State Committee for Hydrometeorology and Environmental Control will no doubt pay attention.

Vera Rich

Corporate research

Monsanto goes for independence

St Louis, Missouri

THE Monsanto Chemical Company's new \$150 million Life Sciences Center in Chesterfield, St Louis, opened this week and will employ 1,200 scientists, engaged mainly in basic biological research, by 1987. About one third of the scientific budget of the company is earmarked for biotechnology research, and Richard Mahoney, Monsanto's chairman, is prepared to invest \$25–\$75 million before seeing a return in the marketplace, at least ten years from now.

The first commercially-produced biotechnological product will be a bovine growth hormone (methionyl bovine somatotropin, MBS) which will increase milk yields by 15–20 per cent, thus allowing farmers to reduce the sizes of their herds. But the blue-suited Monsanto managers are most proud of their company's commitment to basic research, in which they claim now to be self-sufficient. The basic biology of the MBS development had to be contracted out to Genentech.

Monsanto will, however, continue supporting university research programmes, including the 5-year \$23 million collaboration with Philip Needleman's group at Washington University (St Louis). Here, the discovery in the mammalian heart of atrial peptides affecting sodium balance and smooth muscle tone (*Science* 223, 67; 1984) has led to current investigations of the role of these peptides in human blood pressure control.

Roof-top greenhouses and 123 "growth chambers" at the new institute are the two most visible signs of the company's investment in plant genetics and physiology. In plants, expression of genes via the soil

bacterium *Agrobacterium tumefaciens* may eventually confer characteristics such as insect or disease resistance and increased seed production; now Monsanto is extending its earlier work on pea plants (*Science* 223, 838; 1984) to petunia and tomato. The commercially attractive goal of expressing genes in monocotyledonous plants is, however, well advanced in European laboratories; altered *A. tumefaciens* plasmids can be expressed in asparagus (see *Nature* 311, 594; 1984) and plants of the Liliaceae and Amaryllidaceae families (*Nature* 311, 763; 1984).

At last week's opening ceremony, Frank Press, president of the National Academy of Sciences, endorsed Monsanto's research investment, but warned of the dangers of an imbalance between federal and industrial research spending. (Industry now spends more on basic research.)

Press attacked the government practice of supporting work by a single investigator in a single department, and stressed the need for a different basis for the US grant system. Monsanto is ideally placed to make the massive financial investment needed for a multidisciplinary attack on scientific problems and says it intends to continue publishing its research promptly in the scientific literature.

It claims to have learned from past mistakes in the arena of public opinion, being eager to comply with the National Institutes of Health guidelines for recombinant DNA research and preaching the benefits of biotechnology research to the public. So long as it remains open about its work in this highly competitive area, this huge boost to basic biological research will

Spanish universities

Reforms beginning to work

Barcelona

SPANISH universities are in a state of upheaval. The effects of last year's Law for University Reform are making necessary important changes in the structure of universities, affecting in particular the teaching staff, the number of departments, the statutes of the universities and their control.

Just before the end of the academic year, steps were taken to reduce the number of professors under contract and to give some of them tenure (see *Nature* 308, 395; 1984). Commissions were appointed for each discipline, which then decided who qualified for permanent positions. The results now published show that around 6,000 out of 8,000 candidates qualified, a proportion that the Ministry of Education believes accurately reflects the situation.

Mount Wilson Inc.

Washington

A CALIFORNIA industrialist has formed a corporation to take over the Mount Wilson observatory. The present owner of Mount Wilson, the Carnegie Institution of Washington, which also operates the Las Campanas observatory in Chile, announced this summer (see *Nature* 15 August, p.88) that it can no longer afford to keep both sites and will shut down Mount Wilson on 1 July 1985 unless a new owner can be found.

The new corporation, called the Mount Wilson Research Corporation, was founded by George Roberts, who made his fortune designing and manufacturing aircraft lavatories. His company, INCA Corporation, also made the zero-gravity lavatory for the space shuttle.

The corporation has no funds as yet, but hopes to raise an endowment of several million dollars, earnings on which will provide the basic annual operating costs of the observatory. Foundations and individuals are being approached for contributions.

According to Dr Arthur Vaughan, one of several research astronomers associated with Mount Wilson who are involved in Roberts's effort, the corporation is talking to universities and organizations such as the Smithsonian Institution and the Jet Propulsion Laboratory about entering into a consortium.

Vaughan said that the aim is both to maintain an in-house research staff at Mount Wilson and to serve the needs of outside researchers. To that end, all principal investigators would be involved in managing the use of the facility. The board of directors is to be made up of non-astronomers who will be concerned largely with the financial health of the corporation.

Stephen Budiansky

The results varied considerably between the different commissions, and although there was no obvious difference in the quality of the candidates, acceptance rates varied between around 50 per cent and more than 80 per cent. Those not selected are preparing to do political and legal battle. There will be more positions next year, and the situation of university professors will have changed profoundly in a period of only two years. Some people fear the long-term effects, particularly because the number of students is beginning to decrease and there is a danger of saturation of university positions soon.

The statutes of universities will have to be adapted to the new regulations. All universities have been asked to make proposals, and these will have to be approved by the government. The body in charge of this task is the General Assembly (Claustro) which includes professors, students and administrative staff. In some universities, conflicts have arisen between diverging interests.

An important change in the structure of universities, which will be reflected in the new statutes, is the definition of university departments. There is widespread agreement that the present departments are too small and too numerous, having mostly been built around a single professor. It is hoped that the new regulation will stimulate the concentration of people, administration and equipment in order to build up more efficient structures.

From now on, departments should have a minimum number of professors (twelve in the latest version of the law), and a full-time professor as the head of department. Normally, there should be only one department in any subject in a single university. The names of the departments should in principle correspond to areas of knowledge defined by the ministry. In some cases, these regulations may cause problems, for instance in medicine and engineering faculties where many departments have mostly part-time professors or in departments where the members are physically separated or working in very different research subjects. In any case, the power of full professors ("Catedráticos") will probably be diluted in these bigger departments.

The most important change is that the national government is transferring control of the universities to the autonomous governments of the different regions of Spain. Agreement to hand over the universities to the Government of Catalonia has already been reached. But strong differences still exist about the amount of money to be transferred and, as a consequence, the process is at a standstill. The government hopes that this period of upheaval will result in more dynamic universities.

Pedro Puigdomènech

Star wars killings?

Washington

ALTHOUGH almost all of the \$1,300 million budgeted this year for the Strategic Defense Initiative (star wars) is committed to research projects that have been under way for some time, defence contractors are already sensing a kill. "The Department of Defense has budgeted \$24 billion over the next five years for the Strategic Defense Initiative", reads an announcement from the American Society of Mechanical Engineers (ASME). "Will you find a place in this state-of-the-art cornucopia — expected to be a greater undertaking than the Apollo program?" To help them out, ASME is sponsoring a day-long seminar in Washington in mid-November, featuring briefings from key defence officials to show "how to get in on the ground floor". The admission fee is \$245 a head.

The only new funds to come out of the star wars programme so far are \$6 million to be awarded for an initial "creative effort to develop methodologies for defining alternate architectures". Proposals are due by 1 November; it is expected that more than one contractor will be chosen. The winners will be asked to "develop the strategic defense mission", considering both "treaty constrained and unconstrained threats", and to study various "candidate" anti-ballistic missile technologies.

Stephen Budiansky

Balzan prizes

PROFESSOR Jan Hendrik Oort of Leiden University in The Netherlands (above) has won this year's Italian Balzan Prize for astrophysics. The genetics prize has been awarded to Sewall Wright (95), professor emeritus in the Universities of Chicago and Wisconsin. The winner of the prize for history and criticism of the literatures is Professor Jean Starobinski of the University of Geneva.

Each of the winners will receive 250,000 Swiss francs. In 1985, the three prizes will be awarded for mathematics, palaeontology and history of occidental art.

North Sea pollution

West Germany calls for action

Brussels

WEST Germany faces other North Sea coastal states in Bre en this week with demands to make headway in the next two years on marine pollution and improved monitoring of the ecosystem of the valuable fishing grounds of the North Sea.

Participating in the International Conference on the Protection of the North Sea are ministers from the coastal states (Belgium, Denmark, France, the Netherlands, Norway, Sweden and the United Kingdom), from whom West Germany hopes to extract a political commitment to ratify and strengthen existing international conventions. The European Economic Community is also invited.

The North Sea is at present covered not by one but by several international conventions governing the protection of the marine environment from pollution from land-based sources (Oslo, Paris), from pollution by oil (Bonn) and from dumping (London). Not all have been ratified.

The West Germans stress the danger of latent chronic pollution (accumulation of chemicals) as well as more directly visible pollution such as oil. They are particularly concerned about the ecological sensitivity of coastal waters, river estuaries and mudflats, important feeding grounds for fish and birds.

The discharge of dangerous substances through inland and coastal waters is controlled by the 1974 Paris Convention. In 1976, the European Community also adopted a framework directive on emission standards for industrial waste discharges, but so far only limits on mercury, cadmium, polychlorinated biphenyl wastes, waste oils and lindane (last June) have been adopted, out of a list of 129 dangerous substances.

According to Greenpeace, the environmental pressure group, 1,120 tonnes of cadmium and 1,000 tonnes of mercury continue to flow annually into the North Sea. Twenty-three million tonnes of toxic sludge end up in Rotterdam harbour.

Some 11 million tonnes of largely untreated sewage sludge also end up in the North Sea, with the result that algal growth in the North Sea has increased considerably over the past 5-10 years, according to the West Germans.

The West German proposals also include a system for licensing wastes, discharges, and international information exchange on the quantities discharged and requirements that the pollution load should be reduced. At the beginning of this year, West Germany introduced a domestic system of fines for pollution of the North Sea.

According to the West Germans, there is a definite need for further action, including better enforcement and an extension of the Marpol conventions. They also propose that the North Sea be designated as a

special area, that sea dumping should be reduced and eventually dropped. The European Community is preparing a directive banning the dumping of black-listed substances and limiting others.

To combat oil pollution, West Germany proposes a region-wide system of airborne surveillance, improved cooperation in port state control, more use of deep-sea pilots' services and greater compliance by drilling rigs with rules the oil content of effluent.

West Germany also wants to extend research and development programmes to include more biological monitoring and the sampling of more substances. The Paris Commission (the secretariat of the Paris Convention) already monitors mercury, cadmium, polychlorinated biphenyls, oil

from refineries and reception facilities and drilling platforms as well as radioactive effluent from processing plants. The Community intends to start monitoring titanium dioxide wastes next year. West Germany suggests that all this information should be collected in an international database.

Community support for the West German proposals is important, if only because Community directives are binding on member states, whereas conventions enter into force only when ratified. It is therefore unfortunate that, in the case of the draft directive on accidental marine spills of oil and other dangerous substances, now under discussion, West Germany, together with Belgium, Denmark, the United Kingdom and France, feels that a Community directive is neither "necessary nor desirable".

Anna Lubinska

No canker cure from China

Washington

US DEPARTMENT of Agriculture (USDA) scientists working to combat the citrus canker now rampant in Florida (see *Nature* 27 September, p.293) are frustrated by a ban on new agricultural science exchanges with China. The US scientists were hoping to use a symposium planned for this month in China as an opportunity to collect new citrus germ plasm, possibly including canker-resistant strains. But the symposium has now been called off, and researchers are wondering whether the ban will be lifted in time to plan a visit for 1985.

The ban was ordered a year ago by the under secretary of agriculture for interna-

tional affairs, Daniel Amstutz, in retaliation for a Chinese decision to cut imports of US grain, breaking a contract. At the time it seemed likely that China would suffer more from a ban than the United States. The Chinese action was in turn a retaliation for US limits on textile imports.

Southwest China is believed to be the region where both citrus plants and citrus canker originated, according to Dr Jack Hearn of USDA's horticultural research laboratory at Orlando, Florida. American and Chinese scientists last year exchanged plant materials of interest, but citrus canker had not then appeared in the United States.

Tim Beardsley

Whaling

Japan pleads to carry on

Tokyo

THE Japanese Government is to try again to persuade the United States not to retaliate if Japan breaks the whaling quotas set by the International Whaling Commission (IWC) earlier this year (see *Nature* 18 October, p.595). Talks will be held in Washington on 1 and 2 November between the director-general of Japan's Fisheries Agency, Hiroya Sano, and John Byrne, director of the US Department of Commerce's National Oceanic and Atmospheric Administration. Earlier attempts to reach agreement ended in failure on 16 October.

As a result, the Japanese sperm whale coastal fishing fleet (owned by the Nihon Hoge and Nitto Hoge companies) put to sea on Friday 19 October. By the following Wednesday, however, before they had had a chance to catch a whale, the four boats were ordered to return home to give new talks a chance of success.

IWC set this year's sperm whale catch quota at zero, in the absence of agreement among the member countries. Japan,

which had been expecting a minimum quota of 400, vital to keeping its coastal industry going, thus considers it has been unfairly victimized by pressure from conservationists elsewhere.

The Antarctic Ocean minke whale quota was also cut, this time on a scientific recommendation, to a level that would give Japan a share amounting to 1,941 whales — some 600 fewer than the number at which Nippon Kyodo Hoge, Japan's only far-seas whaling company, says it can sustain commercial operations. The company is not yet abandoning whaling, however, and its mother ship, the *Dai San Nisshin Maru*, set sail from Yokosuka for the Antarctic on Saturday 27 October. It hopes that an agreement can be worked out with the United States before it reaches its catch quota around next January.

If the United States stands firm, then the Packwood-Magnuson amendment will be invoked if Japanese boats break the IWC rulings. Japan's fishing quota in the United States 200-mile zone could then be cut to zero.

Alun Anderson

Seascale hazard

SIR — The letter from Pomiankowski (*Nature* 13 September, p.100) raises two points which he considers introduce doubts about the conclusions of the report of the Black Advisory Group into the possible increased incidence of cancer in West Cumbria.

The first concerns the appropriate index on which to rank the occurrence of lymphoid malignancy in the 675 electoral wards of the Northern Children's Cancer Registry region. The suggestion is that the report was incorrect to include a table showing the wards with the highest incidence rates per 1,000 children, and that using instead the associated Poisson probabilities would have been more appropriate. It is important to recognize that these two sets of figures are not simple alternatives, since they measure different aspects of the disease frequency. The rate per 1,000 is a direct measure of the proportion of children under 15 years of age registered with lymphoid malignancy over the period 1968–82, which gives 9.73 per 1,000 in Seascale — calculated on the basis of a total of four cases during the 15 years and the 1981 census population. The cumulative Poisson probability, on the other hand, is a measure of the chance of finding the observed rate (or an even greater one) if the true (rather than the estimated) local ward rate were the same as the overall regional rate of 0.61 per 1,000.

The first index is an assessment of the average risk of a child in the area developing lymphoid malignancy before 15 years of age, whereas the latter is an indication of how unlikely it is that the raised rate in Seascale could have occurred by chance under a particular hypothesis. Each of these indices has its role and importance. In the case of a small-sized population and a small number of cases, the observed rate is subject to sampling fluctuation — and the associated Poisson probability helps to assess the size of this. Both figures are therefore informative and are given in the report. It is not true, however, to refer to the latter as representing the "incidence" of lymphoid malignancy — as was done by Mr Pomiankowski.

The second point concerns two childhood cases of lymphoma in Seascale registered since 1982. It is said that the exclusion of these from the calculations of rates and Poisson probabilities is "disturbing". The figures given in the report were provided by Dr Craft and his colleagues from the Northern Children's Cancer Registry for the years 1968–82. At the time (late 1983/early 1984) when these figures were being prepared, it was too early to include comprehensive cancer registrations beyond 1982 over the whole Northern Region since there is inevitably some delay in the notification of cancer cases to the regional register and, thus, in the availability of complete annual records for inclusion in analyses. For this reason it

is premature to consider the effect of these two cases — known about because of the special attention to the village — on the ranking of Seascale: it remains to be seen whether or not further cases of lymphoid malignancy have moved other small communities up into higher rankings, either of rates or probabilities. No doubt Dr Craft and his colleagues will do this in due course, and make further assessment of the situation possible.

Defining length

SIR — On 21 October 1983, the Comité International des Poids et Mesures (CIPM) promulgated a new definition of the metre as: the length of the path travelled by light in vacuum during a time interval of $1/299\,792\,458$ of a second¹. This new definition raises some fundamental and practical problems.

At the fundamental level, one must reformulate Einstein's second relativity postulate: "Light is always propagated in empty space with a definite velocity which is independent of the state of motion of the emitting body"². For Einstein, this was an empirical fact. Now, this has become a definition and the corresponding empirical fact is that the length of a solid body depends neither on its spatial orientation, nor on the inertial frame where that body is at rest. (For example, in Michelson's celebrated experiment, the length of the arms of the interferometer did not change as that instrument was rotated or as it was carried by the Earth in an orbit around the Sun.) It is easy to derive the Lorentz transformation law from the above postulate.

On the practical side, this new way of defining length implies that there must be two *synchronized* clocks at the extremities of the measured object, in order to determine the corresponding time interval. As synchronization is best performed by light signals², this effectively means that in order to measure the length of an object, one ought to observe the round trip time of a light signal and divide the result in two.

Moreover, the return trip of the light signal must follow precisely the path along which the signal was sent. This is because a closed path surrounding a nonvanishing area (with a suitable set of mirrors) yields a result depending on the direction of travel, if the body being measured rotates. The difference in travel time (clockwise versus counterclockwise) is³

$$t = 4\omega A/c^2,$$

where ω is the angular velocity and A is the surrounded area.

If this effect is ignored (the round trip rule is not even mentioned in the CIPM recommendations!) the circumference of the Earth at the Equator is 123.9m longer if

measured eastward than if measured westward.

Red Sirius

SIR — The recent correspondence (*Nature* 6 September, p.8) concerning the colour of Sirius reminds me that in the ancient astronomy of Iceland, the star was called Loki's Brand, obviously because of its periodic disappearance into the "underworld", but also because of its flaming colour. This apparent colour-naming is therefore not just a Greek phenomenon, but something which doubtless has considerable significance.

Mount Wilson costs

SIR — Your report (*Nature* 15 August, p.88) on the Carnegie Institution's plans to sell the Mount Wilson Observatory understates the scientific importance of this facility and overstates its operating costs. The \$1.56 million budget for Mount Wilson listed in the Carnegie Financial Report — apparently your source for this figure — includes all astronomers' salaries, fellows' salaries and support operations both for Mount Wilson and for the Las Campanas Observatory that Carnegie operates in Chile. A California consortium hoping to operate Mount Wilson asked the director to estimate operating cost for Mount Wilson alone. A detailed estimate, made by our business manager, was produced: \$0.75 million per year. This includes the fraction of all engineering and support services spent on Mount Wilson, but of course not those devoted to Chile.

Many individual astronomers and a number of organizations within and outside the United States have inquired about obtaining all or part of Mount Wilson Observatory. The reason is that it is an excellent site for stellar and solar astronomy. Your implication that this work is less exciting than extragalactic astronomy simply reflects a bias, one that is certainly not shared by all astronomers.

At the recent (October 1984) European meeting on solar physics, the current Mount Wilson solar and stellar research was described as vital, and a resolution was adopted urging that all possibilities for its continuation be explored.

Can Europe avoid the Space Station?

from Erhard Keppler

The European nations could easily be tempted into a very expensive alliance with the United States to produce a space station. But is it worth it?

LIBRARY COMPLEX
Departments of
Chemical Engineering
Chemical Technology
Plastics and Rubber Technology

RECENTLY, there have been talks between the US space agency, NASA, and various European governments in which the American side has aimed to reach agreement with European countries to share in the proposed US Space Station project, in particular its costs.

The space station is supposed to be a large facility in a near-equatorial Earth orbit, about 300 km above the surface. It could be composed of many smaller units launched separately but docked together in space. Such units may, according to NASA's futuristic view, reach dimensions of hundreds of metres in length. One possible configuration of such a station is a long tube, bent into the circumference of a wheel with spokes towards a centre for stabilization and finally put into slow rotation to provide centrifugal forces in the tube to substitute for the gravitational force on the Earth's surface.

On this view, a space station would have a crew ranging from 10 persons at the beginning to perhaps 100 some years later. The first station would, according to NASA plans, become operational in about 1992, and could (again according to NASA statements) serve either as an operational base for launches of Shuttle-launched spacecraft into other orbits, as an Earth observation station or possibly as the first stage towards a production facility in space. These are the essentials of the arguments put forward in support of NASA's space station, the costs of which are established to be about \$11,000 million in the next eight years.

Because of the uncertainties attending such projects, these cost estimates may easily grow to remarkable numbers, as has been shown during the development of the Space Shuttle. NASA's offer to the Europeans is then to participate in the development and manufacture of a space station within a cost-envelope of several thousand million dollars.

The offer has put Europeans in a difficult position. First, Europeans, who had their first experience of manned spaceflight only recently in the first Spacelab flight, are unable as yet to make a sound judgement as to the benefits of this endeavour especially as the second opportunity for a Spacelab flight is not due until 1985. In any case, large numbers of flights are ruled out by the tremendous costs per flight, now more than DM100 million (£25 million). At the same time, it is to be assumed that the US side will not support an eventually suc-

science by providing them further support, frequent flight-opportunities, for example.

Second, Europeans are afraid that the United States may eventually achieve a major success by using their space station commercially (for satellite launches, production and so on) so giving US industry better conditions by, for example low charges, so that European companies might be put at a competitive disadvantage. Thus it may turn out that two-step launches (from ground to a space station and from a space station into geostationary orbit) are much cheaper than direct ascents. Then European space companies would have no chance to compete with US companies in the vital communications market. But such apprehensions have no real basis; they are games in sandboxes.

Third, the conglomerate Europe has so far not been able to find a common strategy in space research and space technology. European space efforts are rather the sum of some countries' space efforts or bilateral agreements.

The case against

What should Europeans do in this situation? What are they able to do? The following are some of the conditions that must be dealt with, and the consequences which must be considered.

- One remarkable argument for the US Space Station, analogous to European apprehensions, is based on the irrational fear that, because the Soviets may build a space-station and so gain advantages denied to the United States, the United States should also build one just in case.

- The Space Science Board of the US National Academy of Science has rejected NASA's plans for the space station, which military sources consider unduly vulnerable.

- Many European scientists reject the space station because it is scientifically uninteresting and because they are afraid that the high costs associated and with its development and operation will draw away resources which are urgently required for more reasonable research.

So what have we gained so far from manned spaceflight? What is the prospect of a firm and solid basis on which to move further in this particular direction? Interestingly enough, the most frequently heard word in this context is "probably", as in its frequent assertion that the

of a space station, as well as the biological/medical sciences and, last of all, also the Earth observing sciences.

Astrophysics is, however, readily excluded because the required accuracy of observations, demanding constancy of viewing direction, is unattainable from a space station, which will always suffer from vibration due to the motion of the astronauts, from impacts of dust and small particles of meteoritic origin and from thermal tensions and relief. Astrophysics as well as Earth-observation techniques can, however, live perfectly well with unmanned spacecraft, specially because such missions should preferably extend over many years and be carried out in eccentric or polar orbits that will always be forbidden to manned missions because of the radiation load that astronauts would suffer.

Materials science is said to be another candidate customer. Materials scientists have just started to investigate the effects of reduced gravity on various rather elementary processes, which are certainly of high scientific interest. But at this early stage, there is not even the faintest hint that it will be necessary to have production facilities in space. Semiconductors, for example, can be made sufficiently well on the ground; neither crystal imperfections due to growth under gravity nor contamination have so far prevented the industrial production of microprocessors or large memories. There are other limits, of course, but there are also other interesting technical possibilities which may become the starting point for new technological pathways that are perfectly well pursued on the ground. Studies under zero gravity may in any case be satisfactorily continued on rocket flights or from unmanned satellites. The recovery of probes from such spacecraft is a well-proven technique, widely used in military applications. There is no justification whatsoever to mount a costly new programme on such evidence.

Finally, the interest of biology in zero-gravity conditions has greatly lost its attraction in the past few years. Indeed, space medicine flourishes largely because there are astronauts.

Much of the enthusiasm for the manned space station as a zero-gravity laboratory seems to stem from ignorance of what has already been achieved. The new "space science discipline" of materials science is carried on by scientists who have never

do not know about the ingenious robots designed over the years by hundreds of scientists to investigate stars, planets, our Sun or the Earth's atmosphere. Automatic self-controlled sequences (such as opening an oven, removing a melted sample, replacing it by another, closing the oven and repeating the procedure) do not have to be invented afresh. Such simple tasks have been possible for many years.

A physical experiment provides answers to the question for which it was designed. If the answer is negative, another experiment will be set up in order further to attack the problem. The rule is that other questions have to be asked after certain answers have been acquired. It is a fiction to believe that such experiments require the presence of people. If the question asked by an experiment is clever enough, the answers will be "yes" or "no". To design such an experimental set-up so that it will not be disturbed by external measures is a challenge to the skill and imagination of the experimenter.

Passengers

The very presence of astronauts in a space station requires extraordinary efforts. More than half of the cost of the development of Spacelab could have been saved if the systems had been unmanned. But for manned systems, the effort will always be greater than is really necessary, for nobody will take responsibility for endangering people's lives. Efforts of this kind are concerned with the number of subsystems and their redundancy, with their reliability, with the selection of materials (beginning with their outgassing performance) and with endless functional tests, the complexity of which is a nonlinear function of their number. The very size of the system requires an enormous amount of testing; the Spacelab Manual, for example, is several thousands of pages thick.

The requirements of reliability, and the selection techniques and materials, result in extremely high costs for all on-board systems, including instrumentation. But parts ordered to the necessary high standards of reliability have prices higher by factors of 100 than those of commercially available parts. Many are only available in the United States, where they are produced mostly for military purposes. In contrast, unmanned satellites can now be built at relatively lower cost, taking advantage of the improved reliability of modern electronic circuits, even those manufactured commercially. Indeed, the use of the Space Shuttle, a manned transporting system, as well as Spacelab, a manned facility, has in fact inhibited developments that would have led to lower costs. Experiments flown on Spacelab, if they had flown on unmanned satellites, could have cost a fraction of what was paid for them.

But unmanned spacecraft can be launched by Ariane, the European launcher, the development of which would

the Space Station, which will require the exclusive use of the Space Shuttle.

Moreover, European participation in the US Space Station would require European industry to use the expensive electronic parts made in the United States. As for the major part of the job, the life support system, European companies would have to build their share under American licences. The chief developments for European industry in such a participation could well be the production of screws and the bending of sheet-metal into interesting shapes.

In contrast, the development of unmanned space stations would force Europe to become more independent from the United States and could bring about the development of important technologies that are at present not available in Europe, perhaps not anywhere. This does not mean that joint efforts with the United States should not be sought. In the past, they have been fruitful, in many cases. But we should not move towards such cooperation on a space station.

There is no problem in constructing spacecraft in modular principles so that subsystems can be removed from the outside. Such repair can be performed by robots as easily as by men in space. Indeed, robots would be able to perform such repairs in any possible orbit — polar, eccentric or geostationary. There is no argument in favour of manned operations from the "repair" point of view.

Indeed, a recent study at Massachusetts Institute of Technology has recognized that robots, controlled according to anthropomorphic principles, may be the most promising route to future space techniques. This development was started 20 years ago when K. Kleinwächter in West Germany built such a system (called "Syntelmann"). There would have to be commodious communications links to send commands to a robot in space, supposedly to perform some operation. The robot may, for example, have a simulated arm. On the ground, a person would do the same experiment, when sensors monitoring the motion of the person's arm would relay appropriate commands to the robot and cause it to do exactly the same thing: opening a box, moving something, turning it. Such devices are also required on the ground, for operations in toxic environments, for example.

Opportunity

With this starting-point it would be tempting to develop, for example, unmanned spacecraft to support zero-gravity research. All the investigations required at this stage of the research could be accomplished in such a way. It would be necessary to develop sensors to generate images in all parts of the electromagnetic spectrum, from X rays to the far infrared. So as not to increase bit rates necessary in

such as on-board image evaluation, pattern recognition, redundancy reduction in information and the improvement of error detection and error-correcting codes for information transfer would be needed. If Europe, recognizing the enormous potential generally of such developments, were to move into such a direction, this would not only stimulate a broad field of scientific research (including for example, artificial intelligence by the application of the concept of associate memories) but would also require from industry products of high technological standard. The result would be to push European science and technology far ahead of where they are now — far beyond what participation in a space station programme might yield.

So why should Europe move along the dead-end route of the US Space Station? All experts agree that it would indeed be a dead-end. It is true that the idea has generated much science fiction — colonies in orbit, on the Moon or on other planets. But there is no possibility that we will be able to live on any other planet in the Solar System, or on an asteroid or on the Moon. There is no air to breathe while gravity is less than on the Earth, with possible consequences for human physiology. Neither the Moon, nor Venus or Mars have strong magnetic fields, so that their surfaces are bombarded by the full intensity of the cosmic radiation. The Moon has no atmosphere, that of Mars is dilute, so ultraviolet radiation and X-rays penetrate to the ground at high intensity. These two environments are a terrible threat to life. Venus has dense layers of ice clouds (from sulphuric acid) in its atmosphere, and almost 100 bar pressure at the surface, so it is dark and hot there; life would require permanent protection. Mercury is also extremely hot, and the outer planets are dark, as on Earth after sunset. So the dreams of life on other planets are unreal, pure fiction. We will stay on this planet. Why not accept that?

Is it not possible for a continent with the tradition of Europe, with its ability and with more than 300 million people, to stand on its own? Why not break with the traditional policy of imitating what is being done in the United States and, instead, move jointly in a promising direction which has been chosen deliberately by argument, not just by dreams or fears? If political unification is difficult in Europe, it should at least be possible to pursue common technical interests. Why not start with a powerful European space programme, designed to make good Europe's technological backlog, that will eventually generate contributions of general importance to our technical and technological development? Participation in the space station holds no such promise. So let us not participate. □

Recollection of a simpler time

The death of Paul Dirac a week ago is a reminder of the precocious and staggering achievement, sixty years ago, of one of the most diffident of contemporary heroes

THE death of P.A.M. Dirac, in Tallahassee, Florida, on 20 October is a moving reminder of what science was like when everything was much simpler than now. The tale is that, as a shy but clever son of a Swiss-born schoolteacher in Bristol in the West of England, he embarked on a degree course in electrical engineering at the local university, just two months before the First World War ended. With a degree but no job, he took a degree in mathematics, as it were to fill in time. By 1923, with the help of a scholarship and a government grant, he was a research student at the University of Cambridge. And then, two years later, at the age of 23, he had put Heisenberg's quantum mechanics, not then published, on an axiomatic foundation that still endures.

How could so much have been done in so short a time? Luck must be a part of any explanation. Dirac was lucky that his Cambridge supervisor was R.H. Fowler, then full of excitement about the statistical mechanics of stellar atmospheres. Dirac was also lucky that Heisenberg went to Cambridge to talk at the Kapitza Club (then Cambridge's private *phi beta kappa*) in July 1925, and sent Fowler a set of the proofs of his first paper on new quantum theory by the middle of August. Who to ask to read them but Dirac? The real luck, of course, was that the time was ripe for a radical upheaval. Planck quanta were real enough but the old quantum theory of atoms, which worked well enough for atomic hydrogen, was increasingly at odds with spectroscopy.

But Dirac's special contribution to quantum mechanics was its independence of what others were about. Heisenberg's first paper (*Zeits.f. Phys.* 33, 879-893; 1925), the proofs of which Dirac had seen, had set the agenda — how to generalize Bohr's prescription that quantum states are those calculated by classical mechanics which happen to satisfy a quantum condition pulled like a rabbit from a hat. Heisenberg's innovation was to describe the kinematics and the dynamics of quantum variables strictly analogous to the classical dynamical variables — position, momentum and so on.

Dirac's first paper on the subject was received at the Royal Society on 7 November 1925, and published the following month in *Proc. Roy. Soc. A* 109, 642-653 (which says something else about the simplicity of those times). Its

It emphasized that the quantities representing dynamical variables in quantum mechanics are elements in an algebra then undefined, it demonstrated that the circumstance that two variables, say q (for position) and p (for conjugate momentum), do not commute is not an embarrassment (as it had seemed to Heisenberg) but a natural way of making a bridge with the quantities in classical Hamiltonian mechanics called Poisson brackets.

Dirac's achievement in the following five years was staggering. By the time his PhD thesis had been submitted (in the spring of 1926), he had made a first attempt at the problem of relativistic quantum mechanics. This was the train of argument that led to Dirac's relativistic equation of the electron which provided both a natural, not *ad hoc*, way of accommodating electron spin and as clear a prediction that positrons must also exist as any more recent prediction of a particle of matter. Almost in passing, Dirac quantized Maxwell's equations, providing the foundations of a quantum theory of radiation and a model for what is now called field theory.

Throughout this revolution, Dirac's style was distinctive. He was not so much an iconoclast as an adventurous spirit, sceptical of fudges but prepared to see where logic would lead. What else can account for his failure to accept as his own the idiom in which his elders and presumptive betters described the problems facing physics in 1925?

The point is nicely illustrated by Dirac's own algebra for the dynamical variables of a quantum system. Heisenberg had shown that the quantum condition boils down to the simple relation that $qp - pq = i\hbar$ if q and p are, respectively a position and its conjugate momentum (with i the square root of -1 and $\hbar$ Planck's constant divided by 2π). When Born and Jordan had reminded Heisenberg that his quantum equations embodied the rules of matrix multiplication, the three went on to elaborate their doctrine of matrix mechanics.

Not Dirac. The quantum variables were the elements of an algebra whose rules were dictated by the physics. Dirac called them q -numbers (*Proc. Roy. Soc. A* 110, 561-569; 1926) and said this about them:

At present one can form no picture of what a q -number is like. One cannot say that one q -number is greater or less than

that if z_1 and z_2 are two q -numbers... there exist the numbers $z_1 + z_2$, $z_1 z_2$ and $z_2 z_1$ which will in general be q -numbers... One knows nothing about the way the numbers are formed except that they satisfy all the ordinary laws of algebra, excluding the commutative law of multiplication.

At any point along the way, Dirac could have resolved this uncertainty by changing idiom. Representing q -numbers by matrices would have given Heisenberg's quantum mechanics, representing them by differential operators would have given Schrödinger's wave mechanics. But why needlessly particularize?

The scale of Dirac's achievement during this short spell is now not easily comprehended. It is as if he had found a secret window on the foundations of physics, a companion for that through which Einstein looked in 1905. It cannot often have been that a physics textbook (*The Principles of Quantum Mechanics*, Oxford, 1930) should be nothing but a record of its author's research.

Dirac's distinctive style stamps this great book and the generation of students brought up on it — or in its shadow. Dirac himself, however strongly convinced in 1930 that the problems of physics had been solved, seems not to have been filled with proselytizing zeal. Always shy, he seems to have been tragically shy of students. Much of the 1930s were spent in a hunt for some way of ridding calculations of radiation fields of the infinities that bedevilled them. Dirac did not succeed in this herculean task, completed only in 1948 by Schwinger, Tomonaga and Feynmann.

But from this period there survive three novel ideas — the notions that magnetic monopoles may exist, that it cannot be a mere coincidence that dimensionless numbers such as the ratio of electrical to gravitational forces are equal to the age of the Universe (in atomic units) and (as a consequence) that the gravitational constant should decrease with increased age of the Universe (*Nature* 139, 323; 1937). Time, no doubt, will show what happens to these conjectures.

Dirac's style persists. The anonymous reviewer of the first edition of his book (*Nature* 127, 699; 1931) said of Dirac that "he bids us throw aside preconceived ideas regarding the nature of phenomena... we may describe this as the application of pure thought to physics". He was a subversive whose pure thought was more penetrating

Molecular medicine

Therapy by instant evolution

from Robin Carrell

EVOLUTION has modified and refined the structure and function of proteins. An understanding of how this has happened makes feasible the prospect of artificially inducing similar changes to create specifically designed variants of human proteins. As a starter, on page 77 of this issue¹, Rosenberg *et al.* (Chiron Research Laboratories) report the use of recombinant DNA technology and yeast to replace the amino acid at the reactive centre of human α_1 -antitrypsin, a natural inhibitor of protease enzymes. The mutant α_1 -antitrypsin retains the specificity of the natural inhibitor, but promises to provide more effective protection to tissues during inflammatory stress. Of particular interest is its potential to prevent the development of the degenerative lung disease, emphysema, but the independent production of related mutants of α_1 -antitrypsin by two other genetic engineering companies, Transgene, Strasbourg (M.A. Courtney *et al.* *Nature*, in the press) and Biogen, Cambridge, Massachusetts (D. Schindler, personal communication) attests to much wider therapeutic implications.

This focus of activity, follows from the realization² that α_1 -antitrypsin is one of a family of serine protease inhibitors, the serpins, each of whose function is critically determined by a single amino acid at the reactive centre. These protease inhibitors have specific roles in the control of the proteolytic cascades responsible for immune reactions, for coagulation, and for other responses to inflammation. Since it is the aberrant activation of these cascades that underlies many disease processes, there is great medical interest in the possibility of specific intervention by the use of engineered inhibitors.

α_1 -Antitrypsin is the archetype³ of the serpin family which includes the plasma proteins: antithrombin, α_1 -antichymotrypsin, C₁-inhibitor and α_2 -antiplasmin⁴. The structural homologies of the family, together with recent crystallographic studies⁵ of α_1 -antitrypsin, indicate that the serpins all share the same highly-ordered globular structure. A feature of this structure is the exposure of the reactive centre as a loop on the exterior of the molecule. This loop is believed to fix the reactive centre in a conformation that makes it an ideal substrate for the target protease. The inhibitor and its target protease thus form a tight 1:1 complex which can be rapidly recognized and removed from the circulation.

The specificity of each inhibitor is critically dependent on a putative cleavage site at the P₁ residue (see the figure) of the reactive centre of the inhibitor. This was

tive centre of α_1 -antitrypsin, which has methionine at P₁ and is primarily an inhibitor of elastase, with that of antithrombin, an inhibitor of thrombin which has arginine at P₁. Unequivocal evidence that the P₁ residue was responsible for the specificity came from an unusual experiment of nature⁶: a child from Pittsburgh was found to have a bleeding disorder associated with a new genetic variant of α_1 -

Serpin	P ₂	P ₁	P ₁ '	P ₂ '	P ₃ '	P ₄ '	Target
α_1 -Antitrypsin	Pro-	MET	-Ser-	Ile-	Pro-	Pro-	Elastase
Valine mutant	Pro-	VAL	-Ser-	Ile-	Pro-	Pro-	Elastase
Pittsburgh mutant	Pro-	ARG	-Ser-	Ile-	Pro-	Pro-	Thrombin
Antithrombin	Gly-	ARG	-Ser-	Leu-	Asn-	Pro-	Thrombin
α_1 -Antichymotrypsin	Leu-	LEU	-Ser-	Ala-	Leu-	Val	Chymase
Mouse contrapsin	Arg-	LYS	-Ala-	Ile-	Leu-	Pro	'Trypsin'
C ₁ -inhibitor	Ala-	ARG	-Thr-	Leu-	Leu-	Val	Kallikrein

Reactive site sequences of natural human serine proteinase inhibitors (serpins) and two mutants of α_1 -antitrypsin. Cleavage putatively occurs at the P₁-P₁' bond with a specificity of inhibition that is clearly related to the P₁ residue (C₁-inhibitor sequence is a personal communication from J. Travis).

antitrypsin, in which the reactive centre methionine had been replaced by an arginine; as predicted, the mutant α_1 -antitrypsin had lost the ability to inhibit elastase but had become a highly effective inhibitor of thrombin.

The general applicability of this dependence on the P₁ residue was recently demonstrated by Hill and colleagues⁷, from a comparison of the amino acid sequences deduced from the cDNA of mouse and human serpins. Their most remarkable conclusion concerned human α_1 -antichymotrypsinogen and mouse contrapsin. These two proteins have a similar sequence but the human inhibitor has a leucine at P₁ and hence inhibits chymotryptic-like proteases, whereas the mouse inhibitor, with a P₁ lysine, has no antichymotryptic activity but predictably is as an efficient inhibitor of trypsin.

Evolution, in several experiments of her own, has thus demonstrated how to prepare specific inhibitors. Rosenberg *et al.*¹ have applied these lessons to the production of a mutant α_1 -antitrypsin in which the P₁ methionine has been replaced by a valine. Their choice follows from the fact that about one in a thousand northern Europeans has a severe genetic deficiency of α_1 -antitrypsin and is consequently susceptible to cumulative damage to the elastic tissue of the lungs, which results in emphysema. In principle, the defences of susceptible individuals could be improved by intermittent transfusions of α_1 -antitrypsin. Genetic engineers, anticipating this need, have taken the opportunity to produce a modified form of

and so provide improved protection.

The risk of damage to the lungs in both normal individuals and those deficient in α_1 -antitrypsin is heightened by the susceptibility of α_1 -antitrypsin to inactivation by oxidants released by leukocytes or present in cigarette smoke⁴. There is strong evidence that this is due to the oxidation of the P₁ methionine to methionine sulphoxide, with consequent loss of effectiveness as an inhibitor of leukocyte elastase. Improved protection might be provided by the replacement of the P₁ methionine of α_1 -antitrypsin with a residue resistant to oxidation^{3,4} — valine seems a logical choice⁸ for an inhibitor of leukocyte elastase. *In vitro* tests of the mutant that fits that bill support those predictions. Before the material is ready for therapeutic use, several questions will need an answer. Does it matter that the mutant protein, as produced by yeast, does not have oligosaccharide sidechains? Antigenicity will probably not be a problem, but how important is it that the mutant inhibitor is likely to be less soluble and long-lived than the natural form? This will be more of a problem if the material is to be administered by transfusions than if it can be directed to the lungs as an aerosol. A greater problem will lie in the assessment and marketing of an agent whose protective effect, with regards to emphysema, is measurable over years rather than days.

Other related mutants that are at the testing stage may have more immediate medical applications. It can be predicted that the P₁ arginine mutant^{1,6} will be an effective medium-term anticoagulant for individuals with either a genetic or functional deficiency of antithrombin. Here, a shortened half-life due to lack of glycosylation may prove an advantage by increasing precision in the day-by-day control of anticoagulation.

In a wider sense, the new papers underline the rapid growth in the practical applications of molecular biology. When we suggested the possible production of the valine α_1 -antitrypsin³ it was done so almost tongue-in-cheek. Yet 18 months later it has been achieved. The speed with which molecular biology is growing has turned protein chemistry into an adventure rather than threatening it, and has converted the academic exercises of correlating protein structure with function into matters of direct, practical importance. □

Oceanography

Tides, solitons and nutrients

from Melbourne G. Briscoe

TIDAL energy mixes the coastal waters, providing nutrients for biological processes. The mechanism is indirect; the topography of the shelf-break, the stratification of the coastal waters and the tides interact to produce groups of solitons — strong, short, high frequency internal waves — and it is the breaking of these solitons as they propagate inshore to even shallower water that is responsible for the mixing. That is the suggestion offered by H. Sandstrom and J.A. Elliott of the Bedford Institute of Oceanography in Canada¹. Their idea, based on their work on the Scotian Shelf, seems sound but perhaps does not go far enough.

Solitons are so-called because of their similarity to the mathematically precise idea of a non-linear wave that retains its identity and form as it propagates along as a singular bump on the sea surface. However, in most situations an internal wave actually travels as a singular wave of depression, since there is usually a deeper layer of water underneath the pycnocline (the layer where the water density changes most quickly with increasing depth) than above it. As the internal depression on the pycnocline propagates, it tends to disperse into the free-wave components that compose it. This tendency is balanced by the non-linearities that arise from the finite amplitude of the depression and allow the wave to retain its soliton form. This fragile balance of forces is easily realized in equations, can sometimes be simulated in the laboratory, but probably never really occurs in the ocean; I therefore use the word soliton with some reservations.

Solitons are thought to be produced by the surface tide running up against the edge of the continental shelf. The pycnocline overlying the shelf is disturbed vertically by the tidal flows and a depression in the pycnocline begins to travel shoreward. There is some uncertainty about the mechanism that forms the depression: Sandstrom and Elliott consider that the surface tide forms an essentially linear, internal tide at the shelf edge, and that the leading edge of the propagating internal tide is the depression that finally resolves into the soliton¹. The scales of these processes differ greatly. The surface and internal tides (called barotropic and baroclinic tides, respectively, in the oceanographic literature) occur once or twice a day, depending on location, but the wave sequence in the soliton is of just a few minutes period. The horizontal scales of these three processes decrease from thousands of kilometres, to tens of kilometres, to hundreds of metres.

Because of the tidal generation of solitons they can be recorded every 12.4 h in those locations where the semi-diurnal tide

is dominant. One might also expect a spring-neap cycle in the intensities of the process, but I am aware of no good data that confirm this; since the dynamics of the generation of the solitons and of their eventual propagation depend on the strength and depth of the pycnocline, the inevitable changes in the hydrography with space and time probably obscure spring-neap effects.

Surprisingly, solitons are often easy to observe in the ocean. The interaction of wave currents in the soliton with short surface wind waves causes a modulation of the roughness of the sea surface that is visible to the eye and to radar. Landsat satellite images described by C. Sawyer² show that the entire eastern seaboard of North America is covered with a pattern of surface streaks characteristic of solitons. This is especially so in the 50–150 m depth range of the shelf, and is most marked in summer and early autumn, when the thermocline is well developed. (Georges Bank and its surroundings perhaps have the most solitons in the western North Atlantic; does this account for the nutrient supply and the fishing industry on Georges Bank?)

Sandstrom and Elliott propose that the surface tides at the shelf edge are converted to internal tides and then to solitons that dissipate on the shelf¹. They calculate a figure of 6×10^7 J per metre of crest length for their solitons. If extrapolated to the coastlines of the world this yields 1×10^{15} J, less than a third of a percent of the total internal tidal energy, a negligible contribution to the problem of how the energy is

dissipated. On the other hand 6×10^7 J dissipated on a 10 km wide shelf in half a day provides about 50 mW m^{-2} towards the vertical mixing of the water and the erosion of the base of the mixed layer. This is at least ten times the energy supply estimated from internal wave dissipation in the deep sea and several times larger than estimates of the energy available from typical winds.

A.R. Osborne and T.L. Burch³ have described solitons in the Andaman Sea near Sumatra that are 15 times more energetic than the examples of Sandstrom and Elliott. Even if all of the coastlines of the world were covered with such solitons, and all these solitons were dissipated in half a day, this would still only account for 0.3×10^{12} W, just 20 percent of what needs to be dissipated from the surface tide in shallow seas according to G. Miller's calculations⁴. (These take into account surface tide dissipation due to conversion to internal tides or solitons on the shelves for some areas of the world, but not for the North American east coast where so many solitons have been observed.)

So even this extreme estimate of the energetics and dissipation of solitons, we are not much closer to understanding where tidal energy goes, but Sandstrom and Elliott's suggestion¹ of the importance of solitons for shelf-mixing and for the supply of nutrients to the euphotic zone seems plausible on the Scotian Shelf. It may even be applicable to thousands of kilometres of other soliton-covered shelves. □

A masked image of the star β Pictoris taken by R.J. Terrell (Jet Propulsion Laboratory) and B.A. Smith (University of Arizona) using a charge coupled device on the 2.5 m telescope at Las Campanas Observatory, Chile. The bright extended emission is thought to come from a circumstellar disk of silicates, ices and carbonaceous organic material. The disk, seen edge-on, is 40 billion miles across; the star is 50 light years away. This disk is the first of its kind to be imaged directly.

T-cell antigen receptor

The capture of the snark

from Miranda Robertson

WHEN I last discussed antigen recognition by T cells five weeks ago¹, I confined myself to what could be learned from the genes encoding the beta chain of the receptor heterodimer, on the grounds that there was serious doubt about the authenticity of the putative alpha-chain gene isolated by Saito *et al.*². There is no longer any doubt.

In this issue Hannum *et al.*³ report amino-acid sequences from a human T-cell receptor alpha chain that clearly have no homology with the amino-acid sequence predicted from the mouse gene of Saito *et al.*²; moreover, the alpha-chain protein is glycosylated whereas the predicted product of the gene has no glycosylation sites. And at the same time, Chien *et al.*⁴ and Saito *et al.*⁵ announce the isolation from mouse T cells of what both cautiously describe as a third type of T-cell receptor gene: in fact, thanks to the protein sequence of Hannum *et al.*, these genes can be unambiguously identified as alpha-chain genes. Yet the original Saito *et al.* gene², which I shall call the non-alpha gene, has all the important properties expected of a T-cell receptor gene; which leaves us, apparently, with one more receptor gene than the protein data had led us to believe we needed.

Since this surprising finding has given rise to speculation that antigen recognition in T cells may require two receptors, I shall briefly rehearse the arguments for and against such a schema in the context of what is now known about the expression of the alpha- and beta-chain genes, before going on to discuss a paper that contains a detailed analysis of several beta-chain genes and may bear on the alternative possibility of dual recognition by one receptor⁶.

How many receptors?

The notion that T cells may require two antigen receptors originated with the discovery that, unlike B cells, which recognize antigen on its own, T cells recognize antigen only in association with cell surface molecules encoded by the major histocompatibility complex (MHC). Specifically, cytotoxic T cells recognize antigen in association with class I MHC molecules whereas the regulatory T cells — the helper and suppressor cells — respond to antigen in the context of class II MHC molecules. Hence the suggestion that T cells might express two receptors, one for antigen and the other for the products of the MHC.

Under such a two-receptor scheme, the non-alpha gene might encode the MHC receptor. Its relative invariance, which was one of the strongest arguments against it as the alpha-chain gene, would be somewhat less of a handicap to a gene encoding a receptor for MHC molecules. Even so

MHC polymorphism might demand rather more than the junctional diversity generated during the assembly of the separate gene segments encoding the variable (V) region of the receptor (for fuller explanation see ref. 1).

There are, however, more serious difficulties with this interpretation of the non-alpha gene. First, immunoprecipitation of the T-cell receptor brings down only the alpha and beta chains, together with the so-called T3 marker molecule, which is coordinately expressed on all T cells with the alpha and beta chains⁷ and whose major chain, unlike the non-alpha chain, has no homology with immunoglobulins⁸. Second, Chien *et al.*⁴ report that the non-alpha chain is expressed at much lower levels in T cells of thymus and spleen than the alpha- and beta-chain genes. Most serious of all, there is compelling evidence from cellular immunology^{9,10} that a single receptor is responsible for the dual recognition of antigen and MHC molecules.

It remains possible that the non-alpha chain exists as a minor isotype, analogous to the lambda light chain of immunoglobulin — which is also relatively invariant. In that case, however, it ought not to be expressed along with both the other chains in the cytotoxic cell line of Saito *et al.* (B cells expressing lambda light chains do not also express kappa chains). There is, in fact, so far no evidence that the non-alpha product is actually made and expressed on the surface of the cell, and since there are numerous precedents for aberrant transcripts the isotype hypothesis cannot be ruled out. On the other hand, until there is evidence that the non-alpha gene is expressed on the surface of one cell or another, its status as a functional gene must be considered unproven.

How like immunoglobulin?

How then is dual recognition reflected in the structure of the alpha-beta heterodimer? Before considering the structure of the beta-chain V regions, I must first dispose of the question of whether the differential expression of different alpha- and beta-chain gene pools could account for the differential recognition of class I and class II molecules by cytotoxic and regulatory T cells. I have already quoted¹ the evidence that the same beta-chain gene pool is expressed in cytotoxic and helper T cells, and it is now clear that both also express the same alpha-chain genes: the constant-region (C) segment of the alpha cDNA clone isolated by Chien *et al.* from a mouse helper cell is identical to that of the alpha-chain clone isolated by Saito *et al.* from a mouse cytotoxic cell. However, the variable regions are clearly very different

which is to be expected in the light of the evidence for V-region diversity in the alpha-chain protein^{11,12}.

This brings us to the question of how the V regions of the alpha and beta chains might provide a structural basis for dual recognition. The homologies, both in sequence and in organization, between immunoglobulin and T-cell receptor genes, have already been discussed in *News and Views*^{1,13}. Because immunoglobulin recognizes only antigen, however, while the T-cell receptor recognizes both antigen and MHC, one would also expect profound differences. Such differences, chiefly in the pattern of diversity of the V regions, are now reported by Patten *et al.*⁶.

I have already mentioned¹ two ways in which beta-chain V-region diversity seems to differ from that of immunoglobulins: first, there is so far no evidence for somatic mutation in beta-chain genes; and second, there seems to be more scope for diversification during the assembly of the three gene segments encoding the variable region, in that it is possible in principle to assemble V genes either with no D segment or with more than one (for details and explanatory diagrams see ref. 1). What Patten *et al.* now show is that any such mechanisms for increasing somatic diversity of the receptor genes are acting on an already very heterogeneous set of germline V segments.

They have analysed beta-chain V sequences from seven helper cells and find that, unlike the immunoglobulin V segments, which tend to run to family sizes of up to 30, V_β gene families seem not to exceed two or three sequences. Moreover, there is very low homology between families: the least homologous immunoglobulin V segments are about as similar as the most homologous V_β sequences. More detailed analysis of this diversity has shown that it can be attributed to seven hypervariable regions, three equivalent to the classical hypervariable regions of immunoglobulin, two more which also have counterparts in immunoglobulin, and two that are exclusive to the T-cell receptor. From predictions of secondary structure based on primary sequence data, and on the assumption that the tertiary structure will be similar to that of immunoglobulin, Patten *et al.* conclude that the three classical hypervariable regions would, like those of immunoglobulin, form the antigen-binding pocket of the molecule, but giving a deeper cleft; while the remaining hypervariable regions would fall on the exterior of the folded protein and might mediate interactions with MHC molecules.

They further speculate that MHC binding might induce allosteric changes in the antigen-binding pocket that would represent a further source of diversity in the range of binding combinations possible. Some very preliminary unpublished evidence is quoted by Patten *et al.* in support of such allosteric interactions: two T cells recognizing the same antigen in association

with different MHC molecules express different V-region genes.

What next?

At this stage, there are not enough data to justify detailed speculation on the mechanism of dual recognition. If the non-alpha chain plays a part in the recognition of MHC molecules, then one might expect that, unlike the alpha- and beta-chain genes, it would be differentially expressed (if it is expressed at all) in different subsets of T cells. Tonegawa has preliminary evidence suggesting that it may indeed be transcribed only in cytotoxic and not in helper cells. In that case, one would also predict an equivalent non-alpha, non-beta chain mediating the recognition of class II MHC molecules in the regulatory subsets.

With all the relevant genes now isolated — both the genes encoding the MHC mole-

cules that the T-cell receptors recognize, and the genes encoding the receptor that does the recognizing — it should be possible to devise transfection experiments that will answer the questions raised in this article. □

Space missions

Very-long-baseline interferometry takes to the sky

from P.N. Wilkinson

RADIO interferometers have long since surpassed the best angular resolution achievable with ground-based optical telescopes but radio astronomers have continued to strive for higher resolution in the quest of new information about cosmic objects. Since 1967, when the technique of very-long-baseline interferometry (VLBI) was introduced, we have been aware that there is a natural limit to this process — the separation of our telescopes is restricted by the size of the Earth itself. Nonetheless, there have so far been enough scientific rewards from exploiting existing radio telescopes for us not to worry too much about limited resolution.

Now, however, in common with many other astronomers, our thoughts are moving beyond the Earth towards an observatory in space, QUASAT (for QUASar SATellite), which would be linked to the earthbound network of radio telescopes. The initial ideas for this project were discussed recently at a workshop* sponsored by the European Space Agency (ESA) and the National Aeronautics and Space Administration (NASA), attended by astronomers, engineers and administrators from twelve nations.

Much of the present interest in VLBI stems from the recent extension of the principle of 'aperture synthesis' to arrays that span intercontinental distances; as a result, radio maps with milli- and sub-milliarc second resolution can now be made routinely. But many extragalactic sources and components in water-line masers are barely resolved even on the longest Earth baselines and at the shortest wavelength (1.35 cm, a frequency of 22

GHz) at which most large radio telescopes work well. Higher resolution, at least on continuum sources, is achievable at millimetre wavelengths but millimetre-wave VLBI is only in its infancy. To take advantage of the experience at centimetre wavelengths and to use the more numerous and much larger centimetre wave telescopes, the physical length of the baselines must be extended. This can be done only with the aid of a radio telescope in space.

QUASAT's astrophysical importance depends on its sensitivity, and on the resolution and quality of the synthesized image. In this 'first step' mission compromises must be made between these criteria. Thus the present proposal, which is dominated by the desire to observe at 22 GHz, has a relatively small antenna and hence sensitivity at the lower frequencies has been conceded for resolution. Nonetheless, QUASAT would have plenty to look at in its up to 5 year lifetime. The proposed orbit would yield roughly a three-fold better linear resolution, or a 10-fold smaller pixel area in the resulting image than Earth-based arrays. At 22 GHz the resolution is about 100 μ arc s, corresponding to a size scale ranging from 1 AU (the distance from the earth to the Sun) at the distance of the galactic centre (10 kpc) to about 10,000 AU at a distance of 100 Mpc. Computer simulations presented by A. Readhead (Caltech) show that with QUASAT and typical 10-station ground arrays, it would be possible to make radio images of a quality similar to that now achieved with multiple 'snapshot' observations using the Very Large Array (VLA), but with almost 1,000 times higher resolution; and that VLBI work in the

lutionized. Furthermore, using a worldwide network of 34 ground observatories which could be available in the 1990s, it would be possible to produce radio images of the compact nuclei of active galaxies as complex as any that the VLA has so far produced.

There was no shortage of exciting ideas for what the QUASAT mission could achieve. Superluminal sources — in which there are ordered motions with apparently faster-than-light speeds — are among the obvious targets. Even after a decade of observations, we have no real physical understanding of these phenomena. A closely related goal is to study the propagation of the energy-carrying beams, which emanate from the 'central engine' in active galactic nuclei, as they pass through the region that is responsible for producing the broad optical emission lines. We now know that in the much larger narrow-line region, the line-emitting gas clouds can bend and brake the beams; thus the interaction probes the physical conditions both in the clouds and in the beams. QUASAT will extend this study to the broad-line region, which is inferred to be less than a light year across in many cases, and which therefore cannot be studied directly even with the Space Telescope.

On the smallest accessible scales QUASAT could test the long-standing prediction that the brightness temperature of incoherent synchrotron emission is limited to 10^{12} K by inverse Compton scattering. It cannot be tested using Earth baselines but the QUASAT baselines would record 10^{13} K emission if it exists. The super-bright emission could be from a previously unsuspected coherent radiation source or, more likely, it could indicate that the emission region is approaching us at relativistic speed. In this case the apparent brightness temperature in the observer's frame is increased because of the effects of aberration.

Several speakers stressed QUASAT's great potential for studying the physical conditions in hydroxyl (at 1.6 GHz) and water (at 22 GHz) masers which are associated with star-forming regions and some late-type stars. Perhaps the most exciting prospect, however, is to use the water-masers to make fundamental distance measurements. The internal motions of water-maser spots, already revealed by Earth-based VLBI, have enabled the distances of three galactic maser complexes to be measured by statistical parallax techniques (Moran, J.M. *Nature* **310**, 270; 1984). QUASAT would greatly facilitate these measurements and would allow the distances to many more star-forming regions to be determined. And M.J. Reid (CFA) introduced the even more tantalizing prospect of using masers to measure the distances of nearby galaxies, thus helping to clarify the contentious extragalactic distance scale. Powerful

galaxies (Moran, *op. cit.* and Claussen, M.J. *et al. Nature* 310, 298; 1984) and we could use the statistical parallax technique if we could measure their internal motions with an accuracy of a few microarc seconds per year.

With QUASAT, it might also be possible to determine the orbital motions of maser sources around a galaxy. These angular motions (corresponding to velocities of a few hundred km s^{-1}) will be an order of magnitude larger than the internal motions in the masers themselves. If the rotation curve and the inclination of the galaxy are known, then a distance estimate can be derived directly.

One debate at the workshop centred on the scientific trade-offs between raw resolution and imaging capability. A vocal minority took the view that much cruder images, but with two or three times greater resolution, might lead to more fundamental discoveries. Where to draw the line between resolution and image quality is a matter of judgement but clearly more computer simulations are needed to investigate the point at which image quality deteriorates to levels unacceptable to all.

R.Z. Sagdeev (Space Research Institute, Moscow) gave a brief, but up-to-the-minute account of current Soviet thinking. The USSR hopes to place a large (30 m) antenna in low Earth orbit by the end of this decade. This spacecraft, working with ground telescopes in the USSR, would produce a well-filled aperture but with maximum baselines little longer than can be obtained with current VLBI networks. Thus it is being regarded as a step towards a more ambitious mission which might, like QUASAT, be launched in the 1990s. This second mission resembles QUASAT in several ways: for example, it would employ wider bandwidths and higher observing frequencies. It also offers an appealing way around the trade-off between resolution and image quality which inevitably arise when only one orbiting telescope is used. There would be much to be gained if QUASAT and the Soviet telescope (unofficially dubbed KBACAT) were to be placed in complementary orbits. In the most entertaining few minutes of the entire meeting J.F. Jordan (Jet Propulsion Laboratory) showed a time-lapse movie simulation which demonstrated graphically how, in this regard, the QUASAT-KBACAT baselines would enable us both to have our cake and to eat it, for both longer baselines and a better filled aperture plan are then possible.

QUASAT seems destined to be a competitor in the 1987 selection round in ESA and could get a 'new start' in NASA that same year. The antenna concept is expected to be selected in summer 1985, with a joint NASA-ESA phase A study in 1986. Launch could be in 1992. □

Martin Ryle 1918-1984

SIR Martin Ryle, pioneer of radio astronomy and explorer of the Universe, died on 14 October 1984. His insight and originality in radio science was first displayed in wartime, when he was recruited directly from Oxford in 1939 to work in the Telecommunications Research Establishment. Here his first tasks were to develop airborne radar aerial systems and to test equipment for the new centimetric waveband; these provided an introduction to radio techniques which prepared him well for his vital, but almost unrecorded, contributions to radio countermeasures.

It was Jack Ratcliffe who persuaded Ryle to start radio research in the Cavendish in 1945, with the support of an ICI Fellowship. The wartime discoveries by John Hey, of intense radio emissions from the Sun and from a mysterious source in the constellation of Cygnus, provided challenging subjects, well suited to Ryle's experience in the location of radio transmitters and the recognition of unusual signal characteristics. He devised a radio interferometer, analogous to Michelson's optical counterpart and soon named after it, which showed in 1946 that sunspots emit powerful, circularly polarized radio waves, and that the quiet sun is surrounded by a hot, radio-emitting corona. A succession of students was encouraged to map this coronal emission, using ingenious developments of the interferometer; these developments can now be seen as the first stages of the technique of aperture synthesis, one of Ryle's most famous achievements.

The investigation of the Cygnus radio source followed similar lines. It was a natural hypothesis that this source might be a star that radiated like the Sun but much more powerfully. The successful location of the source, and its identification as a very distant and very unusual galaxy, opened the way for radio astronomy to investigate the structure of the Universe on the largest scale. At that time, there could be no clear interpretation of the many discrete radio sources appearing in the early surveys; they were at first supposed to belong to our Galaxy, where they would account for the background radio emission from the Milky Way. Ryle determined to survey and locate a large number of these sources. For this purpose he built a large interferometer array, working at a wavelength of 3.7 m. The results were astonishing: the sky was apparently crowded with sources, with almost no concentration in the Milky Way.

In his 1955 Halley lecture, Ryle showed that most of these radio sources must be extragalactic and so distant that they gave the first clear evidence which could be used to distinguish between cosmological theories. His results and their interpretation were immediately the subject of

not agree with the number counts of the radio sources, while the theorists vigorously defended the sinking ship of the Steady State. The conflict could only be resolved through better observations, which Ryle duly provided by improving the interferometer in successive steps, leading eventually to aperture synthesis.

Aperture synthesis, the simulation of a very large radio telescope by the use of multiple interferometers, was Ryle's supreme invention. It was achieved in 1956, when the technical problems of computation were overcome by the use of the pioneering digital computer, EDSAC. Its full development progressed through the 'one-mile' telescope (1964), which used three 18 m paraboloids, giving an angular resolution better than one arc minute, to the well-known 'five kilometer' telescope (1972), working on shorter wavelengths: this telescope gave, for the first time, an angular resolution of one arc second, similar to that of optical telescopes.

The results, both in the form of number counts and as detailed maps of radio galaxies and quasars, firmly established radio astronomy as the main source of direct observational evidence in cosmology. There were, of course, many by-products, most notably Hewish's discovery of pulsars, which led to Ryle and Hewish sharing a Nobel prize in 1974.

Ryle's originality and determination marked the whole development of Cambridge radio astronomy. He was a magnetic figure, with the power of inspiring of a deep loyalty and a social cohesion among a long succession of students. He had a deep social conscience, which led him in his later years to an active and public concern about nuclear power and armaments. He will be remembered with affection by everyone who worked with him.

EARTHQUAKE MEASUREMENT

IN an article on "Earthquakes" in last week's *Nature* (p. 608), Dr. H. J. Johnston-Lavis takes exception to the records of earthquake motion which I have published, on the ground of their complexity, and pronounces the Plain of Yedo unsuitable for earthquake observations.

Now this seems to me to be a very eclectic way of treating earthquakes. We can measure earthquakes only where we find them, and I suppose the first qualification in a site for an earthquake observatory is that there should be plenty of earthquakes. The Plain of Yedo possesses this qualification in a very high degree; and if the disturbances which occur in it are of a very much more complex character than our *a priori* notions about earthquakes may have led us to expect, it is not the Plain of Yedo that is to blame.

Anthropology

Prehistory of Amazonian Indians

from Robert M. May

TIME was when the popular image of the Amazonian rain forest was of a teeming paradise with great potential for sustained productivity. Following the collapse of many ill-conceived 'development' projects, however, the contemporary image is more one of fragile forests perched on impoverished soils, or even of a Green Hell¹. Consistent with this recent picture is a vision of the Amazonian Indians as simple people eking out a precarious existence, with population densities that have always been too low to sustain any complex social organization or culture. A series of recent studies contest this view of the Amazonian Indian²⁻⁶. Several studies argue that prehistoric population densities were an order of magnitude or more higher than conventional estimates, or than densities found today. Moreover, it is argued that the Indians' knowledge about and use of their environment was much more sophisticated than has usually been believed.

Population

The early estimate of the density of aboriginal Indians in Amazonia before the advent of Europeans was less than one individual per km². As summarized by Dobyns² in an important revisionist article, this estimate is based partly on historic records, partly on assessment of the carrying capacity of the environment and partly on direct observations of contemporary densities of aboriginals. Dobyns discusses each of these three approaches.

First, most historians and anthropologists have tended to discount contemporary sixteenth and seventeenth-century estimates of Indian populations in both North and South America as gross exaggerations. Another revisionist, Myers³, is understanding of such discounting, even though he disagrees with it: "we must recognize that the earliest historical sources were written either by adventurers in search of gold and kingdoms to conquer, or by missionaries whose vast expenditures could only be justified by a proportionate number of conversions to the Catholic faith. When disinterested parties finally did reach the Amazon, they found no evidence of the large populations which were reported to have lived there". Dobyns shows, however, that when the old records — or indirect inferences drawn from them — are examined carefully, and cross-checked one against another where possible, their high estimates of the initial size of aboriginal populations in North America, in Central America, in the Incan Empire and in Amazonia appear to stand up. Discrepancies arise because populations crashed between first contact and the arrival of

diseases introduced by Europeans. Likewise, Myers's detailed analysis of all available historical records for the Indians along the Ucayali River in eastern Peru indicates that "large and stable communities were in fact characteristic of the mainstream Ucayali tribes at the beginning of the historic period, but that they collapsed with the precipitous population declines caused by Spanish diseases".

Second, our understanding of the ability of the Amazonian rain forest to sustain humans is not good enough to provide any reliable estimate of population sizes (more on this below).

Third, direct observations of population sizes several years after European contact are not useful, by virtue of the havoc

Buhaqana Indian, East Colombia, c.1890. (Peter Newark's Western Americana).

wrought by disease. Such useful observations as do exist come from geographically isolated areas of the Amazon Basin where a few native populations appear to have experienced their first effective contact with Europeans so recently that ethnologists have been able to collect information about the population before contact. One group, first contacted in 1926, was virtually wiped out by influenza in 1929. In another, 300 died of pulmonary oedema in 38 hours. Another group of 300 Sabane came into a Brazilian post, where the wagon bringing gifts and rations for them also brought bronchial pneumonia; the few survivors fled back to their settlements, spreading the epidemic. Anecdotes of this kind make it clear that

decades after first contact give little hint of pristine population densities².

In pursuit of an estimate of the depopulation typically caused by disease, Dobyns pulls together information from various places in the New World and concludes² that over the 100 years following first contact, "the depopulation ratio of 20 to 1 appears to be a sound, if perhaps conservative, tool to employ as a hemispheric minimum". This figure coincides with an earlier and less encyclopedically-based estimate by Borah of a 95 per cent reduction by disease in native populations².

As Myers has emphasized elsewhere, viral and bacterial diseases can travel along trade routes, accompanying items of trade into remote regions long before the first face-to-face contact with Europeans is made⁴. Thus, the first reported contact may be with a native population already severely reduced by disease.

A different and independent indication that Amazonian Indian populations were relatively dense before the arrival of Europeans comes from analysis of sites of 'Indian Black Earth' (*terra preta do indio*)⁵. These patches comprise black earth intermixed with potsherds and stone stools; they are scattered throughout the Amazonian Basin and are classified as a soil type. Suggested explanations of the phenomenon include fallout from volcanos, sediments from vanished Tertiary lakes, remnants from slash-and-burn agricultural practices and cultural layers accumulated at former Indian villages. Smith argues persuasively that the first three explanations are not consistent with the observed geographical distribution or the depth and composition of the patches⁵. He concludes that the *terra preta* sites are the vestiges of ancient cultures in Amazonia, providing evidence that "precontact native populations were in many cases large and sedentary, particularly along rivers". If this is so, says Smith⁵, "biologists should be wary when they discuss virgin Amazonian ecosystems. Potsherds and black earth may lurk under control plots and pristine nature reserves".

Lifestyle

Not only may the early Amazonian populations have been more dense than previously thought, but it also seems likely that they were correspondingly more sophisticated. In particular, the fieldwork of Posey on the Kayapo Indians in Central Brazil has illuminated these peoples' rich appreciation of their environment⁶. The present population consists of about 2,500 Indians inhabiting 9 villages scattered within a 20,000 km² reserve.

Like most such people, the Kayapo have a large vocabulary to describe the subtleties of their surroundings. Their major subdivisions of the forest include *ba-kamrek* (riverine forest), *ba-epiti* (higher forest subject to intermittent flooding every 10 years or so, but containing some richer

alluvial soils), *ba-kati* (*terra firme*, lands that do not flood) and *ba-rarara* (forest with intermittent openings). Kayapo villages are sited to have access to a variety of these ecological zones, and the patterns of field ownership read like something from a current behavioural ecology text: although some fields are selected from *ba-kati*, others are carved from *ba-epti* because the better yields offset the unpredictable losses due to flooding; chiefs' fields and womens' collective fields are usually planted in such a way as to minimize total crop loss for any one family group. Not only do the Kayapo utilize some 250 plant species for their fruits, along with several hundred others for their nuts and tubers, but they also practice a transitional form of cultivation. In addition to cultivated plots near the villages, men on hunting treks rely on 'islands of resources' along their vast network of interlinked forest trails; these 'forest fields' are maintained by collecting plants during the day's travels and then replanting them near established campsites. At least 54 species of these semi-domesticated plants are used in the forest fields.

The Amazonian Indians also know their animals: "every significant detail of the life habits of animals is part of [the] hunter's knowledge, including the sound of its cry, its preferred foods, its excrement, its scents, the teeth marks it makes on fruit etc"⁷. Beyond this, the Kayapo practice a transitional form of domestication of animals. Thus, they deliberately stack the remains of banana and palm plants near villages to attract adult beetles that lay eggs in such refuse; in due course, the Indians know when to collect the tasty and nutritious grubs that mature from the eggs. The Kayapo further recognize some 54 species of stingless bees and 2 species of stinging bees: some of these are cultivated for honey and beeswax, and other species are cultivated (in rotting logs in holes dug in fields) as pollinators to increase crop yield.

Although little is known about the medicinal and other properties of the Kayapo's cultivars, at least two merit mention. The red seeds of *urucu* (*Bixa orellana*) are used to flavour foods and also as the main ingredient in body paint. Red body paint is widespread for adornment throughout Amazonia, but Posey also found *urucu* "to be an effective natural insect repellent with a significant reduction (as much as 84 per cent) in insect bites when painted on the body"⁶. The wild ginger *madn-tu* (*Zinziber*) is used — apparently with some effect — as a medicine against intestinal parasites.

Posey takes to task the common misconception that fields cultivated under slash-and-burn agriculture are totally abandoned after a few years. Kayapo 'abandoned' fields continue to produce harvests of yams and taro for 5–6 years, bananas for 12–15 and *urucu* for 20 years or more. The reforestation sequence also produces a variety of foods that attract

game in artificially high densities, and this phenomenon is also exploited. The Kayapo "thus do not have a clearcut demarcation between fields and forest, nor between wild and domesticated. Rather they have a more general system for classification of ecological resources that forms a continuum between wild and domestic ones, all of which figure into integrated management strategies"⁶.

Posey also tells some fascinating tales of the way myth and ritual interweave with natural history facts. One example must suffice. The myth: the little red ants are gentle like women and they are the relative/friend of the manioc; this is why women use the little red ant to mix with *urucu* to paint their faces in the maize festival; the little red ant is the guardian of the field. The facts: manioc has extrafloral nectaries that attract the ants, which in turn trim away any bean vines that would prevent the new and fragile manioc stems from growing; the beans can climb on the maize, which is sturdy enough to shoot up undamaged; and the leguminous beans help

fertilize the total crop. Thus, the coevolutionary relation of ants to the manioc-maize-bean system does indeed facilitate the women's work.

It is tempting to go beyond this, seeing such myth and ritual as functioning to regulate the Indians' use of natural resources. Although this may sometimes be so, I do not always find Posey's argument compelling: the Kayapo 'belief system' may simply serve to describe the world, rather than to manipulate it. Even so, such finely-nuanced description puts these people closer to the contributors to *Nature* than is commonly conceded. □

Nomenclature

Code for Spanish names of birds

from I.F. Aguillo and M. Fernández-Cruz

ALTHOUGH publication of the International Code of Zoological Nomenclature was one of the most important achievements of modern taxonomy, vernacular nomenclatures remain useful as a communication tool; common names often hold a lot of information, as they represent a particular aspect of the relationship between man and his environment. The use of vernacular names is particularly common in the case of ornithology, a science with a high number of amateurs and much non-scientific literature. In that sense, ornithologists use both common and scientific names in their papers, giving special value to the former as an informative tool.

There is a great vernacular richness associated with birds, in every language and region of the world. The amount of information available is so large and varied, that quite often it is necessary to accept widely used names that are not as informative as they could be. This is not the case with the Spanish-speaking community of ornithologists, probably because the scientific infrastructure of the regions and the ornithological bibliography available in Spanish are very scarce. Thus the situation is favourable for the vernacular nomenclature of birds to be modified so that the names are more meaningful.

Since there are very few lists with accepted names in Iberoamerica, it will first be necessary to make a checklist to be used as a reference by all of the members of the community. Such a project has already been launched but its success will require the international cooperation of all 20 or so

countries integrated in this community. The ultimate aim is to produce a system of common names for the Iberoamerican and European avifaunas, based on associative and meaningful names.

General agreement has led to the proposal for a unified Code of Spanish common names which states the rules for deriving the new nomenclature. Although its criteria are inspired by the International Code of Zoological Nomenclature, informative names will be favoured over priority ones. Names will be brief and easy to write and pronounce; and will be selected on the basis of how informative they are.

The unified nomenclature will be binominal. The first word will be the 'generic name' which refers to all those species that can be grouped in accordance with taxonomical, morphological or historical-usage criteria. Preferably, the name should be derived from the vernacular roots of the community people, adapting it to the Spanish language. In other cases, the name will include information about ecology and ethology of the bird, but not morphological information. The 'specific name' will follow as an adjective, will characterize each species, and represent it in every way. This name will include information about the bird's morphology and appearance, geographical distribution and so on.

The Code and details of the proposed unification project, in Spanish, are available from the authors at: Cátedra de Vertebrados, Facultad de Biología, Ciudad Universitaria, 28040 Madrid, Spain. □

Solid-state perspectives of the photoelectrochemistry of semiconductor-electrolyte junctions

F. Williams* & A. J. Nozik

Solar Energy Research Institute, Golden, Colorado 80401, USA

More than one mechanism is required to account for the photoinduced movement of charge across semiconductor-electrolyte junctions. Distinguishing the various mechanisms, which is here accomplished using a synthesis of theoretical ideas from both solid-state physics and electrochemistry, may have important consequences in research related to potential applications of liquid junction devices in solar energy conversion.

PHOTOEXCITATION of semiconductors in contact with liquid electrolytes, followed by charge transfer of the photogenerated carriers into the liquid, is an important and well-studied phenomenon. This process can occur via several mechanisms which are generally not clearly differentiated in the literature. Furthermore, there are important similarities, as well as differences, between photoexcited semiconductor-electrolyte, semiconductor-vacuum, and semiconductor-solid systems. In this review, we discuss the mechanisms for photoexcited charge injection within a common framework, and connect the phenomena with other well understood semiconductor concepts. In addition, we provide a glossary of terms that joins the languages of solid-state physics and electrochemistry and will help readers of either discipline with the language of the other.

Two major phenomenological regimes can be identified. If the photoexcitation creates charge carriers with energies sufficiently large to be injected into continuum states of the liquid, then this process is defined as photoemission (PE). On the other hand, if the photoexcitation energy is sufficient to bridge the semiconductor band-gap, but insufficient for emission to occur into a continuum state of the liquid, the photogenerated carriers can still be injected into the liquid. This process occurs by charge separation and transport facilitated by the existence of a space charge (depletion) layer at the semiconductor-liquid interface; the process provides the basis for photoelectrochemistry. We call this process photoinduced charge transfer (PCT).

Photoemission

Photoelectric emission from a semiconductor into a vacuum is well understood. The simplest systems for analysis have no surface charge or space charge and their electronic states and transitions are illustrated in Fig. 1. The vertical axis represents total energy of an electron (eigenstate of the electronic hamiltonian) and the horizontal axis is position perpendicular to the surface. Within the semiconductor, the highest occupied band state at equilibrium is the top of the valance band E_v ; the lowest unoccupied state is the conduction band edge E_c ; the two are separated in energy by the forbidden gap E_g . The energy of an electron just outside the semiconductor, with zero kinetic energy, lies above E_v at the photoelectric threshold E_0 , often referred to as the vacuum level. The Fermi level E_f describes the thermodynamic occupancy of all electronic states, including dopant states within E_g .

In the photoemission measurements, the semiconductor is illuminated with photons of energy $h\nu$ and electrons are emitted into the vacuum and collected by a metal at an applied voltage

V with respect to the semiconductor emitter. For the metal there is no band-gap and E_f lies at the top of the occupied band states. For both semiconductor emitter and metal collector the work function W is the energy from E_f to the vacuum level. Two experimental conditions are shown: Fig. 1a for a voltage V_i between collector and emitter just sufficient for all emitted electrons to be collected; Fig. 1b, for a voltage V_e which only collects the most energetic electrons. From these measurements the photoelectric threshold E_0 can be obtained:

$$E_0 = W_e + E_f = h\nu + e(V_e - V_i) \quad (1)$$

where $h\nu$ is the photon energy. The work function of the emitter,

Fig. 1 Energy diagram for photoemission from semiconductors into vacuum: a, voltage that collects all emitted electrons; b, voltage that collects most energetic electrons.

* Deceased June 1984. Work performed while on sabbatical leave from Physics Department, University of Delaware, Newark, Delaware 19711.

The language of solid-state physics and electrochemistry

Acceptor dopant: An impurity which, in the neutral state, tends to accept an electron from the valence band, that is, to donate a positive hole.

Adiabatic potential: The effective potential for motion of atoms in a molecule or in a condensed phase, obtained in the approximation that the electrons move rapidly and the nuclei slowly. It consists of two terms: the nuclear-nuclear (or core-core) interactions, plus the eigenvalues of the electron state with parametric dependence on atomic coordinates.

Ballistic electron: An electron which traverses the active region of a device without generating or annihilating a lattice vibration (phonon).

Band structure: The relationship between the one-electron eigenvalues and the quasi-momentum which characterizes electronic states for crystals. For semiconductors a gap of forbidden eigenvalues lies between the occupied valence band and the empty conduction band. If the maximum of the valence band and the lowest minima of the conduction band are at the same value of the quasi-momentum, that is, Γ -points, the semiconductor is said to have a direct gap; if not, that is, lowest conduction minima at X- or L-points—an indirect gap.

Band tailing: The density of states for the band structure of undoped, perfectly-ordered semiconductors decreases rapidly to zero at the band edges. Dopants, disorders, space charges and applied electric fields perturb the density of states leading to tailing from the band edges into the forbidden gap.

Depletion region: The space charge region in a semiconductor which is depleted of majority carriers and produces a potential barrier for their transport to the interface.

Donor dopant: An impurity which in the neutral state tends to donate an electron to the conduction band.

Effective mass: Electronic particles in crystals react to an applied force as if they have an inertial mass which is different from the free-electron inertial mass. This mass is designated as the effective mass. The difference between the effective mass and the free-electron mass is due to the interaction between the electronic particle and the periodic potential of the crystal.

Electron-phonon interaction: The separation of the many-body problem of electrons plus nuclei in crystals into electronic band structure on the one hand and lattice dynamics (phonons) on the other is an approximation. A correction to this approximation involves coupling between the electrons in their states with the lattice dynamics and is called electron-phonon interaction. This interaction is essential for thermalization between electronic particles near their band

edges and for the molecular or lattice dynamics. It is also responsible for the polaron.

Exciton: An excited electronic state of crystals in which the excited electron and the positive hole are coupled (electron-hole pair); no net charge is transported during exciton motion. The effective mass exciton is a coupled conduction band electron and valence band hole: thus optical creation of effective mass excitons occurs on the long wavelength edge of the band-to-band optical absorption.

Fermi level: Energy level for which the occupational probability for an electron is 0.5, under thermal equilibrium conditions. The occupational probability for a positive hole is also 0.5 at equilibrium.

Franck-Condon principle: The most probable optical transitions between electronic states occur on a time scale short compared to the period of atomic motion, that is, molecular or lattice vibrations: the positions and momenta of the atoms remain fixed during these transitions. Franck-Condon transitions occur vertically between adiabatic potential curves for the initial and final electronic states of the transitions.

Helmholtz layer: The double layer of charge created at a solid-liquid electrolyte interface by the adsorption on the electrode of ionic and/or molecular species from the liquid.

Hot carriers: Electrons or holes that are not in thermal equilibrium with the lattice and have energies above the respective band edges, in the form of excess kinetic energy.

Negative electron affinity: Effect produced when sufficient band bending is generated in a p-type semiconductor with a low work function surface layer such that the position of the conduction band edge in the semiconductor bulk is above the vacuum level. Thus, photoemission of electrons into vacuum by band-gap photons can occur if this happens faster than intraband relaxation in the depletion region.

Polaron: For polar semiconductors, conduction band electrons and valence band holes do not move at their respective band edges as pure electronic particles but rather carry with them a cloud of lattice polarization (virtual phonons). The electronic particle bearing lattice polarization is itself particle-like and is called a polaron. The polaron mass is in general greater than the band effective mass, and quantitatively dependent on the electron-phonon interactions.

Positive hole: The ground state of a pure semiconductor has a filled valence band and an empty conduction band. States of excitation are thus best described focusing attention on the small concentration of electrons in the conduction band and/or the small concentration of unoccupied valence band states. The latter are electronic particles called positive holes, often abbreviated to 'holes'.

W_c is obtained from the first of these measurements if the work function of the collector, W_{c1} , is known¹.

The effects of space charge are exemplified by negative electron affinity photocathodes², shown for p-GaP in Fig. 2. Equilibration with several monolayers of n^+ -Cs₂O yields a large degree of band bending in the p-GaP, arising from the difference in work functions of these two materials and yielding a space charge. The eigenstates of the complete electronic hamiltonian, including the field due to space charge, are now more complicated than those described earlier, so that the position-dependent band edges E_c and E_v in the space charge region have a somewhat different interpretation than E_c and E_v in the space-charge-free region. In both regions, conduction electrons and positive holes (empty states in the valence band) which are in thermal equilibrium with the lattice move at energies near E_c and E_v , respectively. Band-to-band photoexcitation with photons bigger than E_g produces electrons with energies above the conduction band edge in the bulk. These electrons relax rapidly in <10 ps, in the flat-band region, and diffuse as thermalized carriers to the depletion region. From within this region, the photogenerated carriers can be emitted, without relaxing, to the conduction band edge E_c at the surface. Thus, electrons with energies in excess of the energies of thermal carriers in the depletion region, that is, non-equilibrated with the lattice at the GaP/Cs₂O interface, are emitted into the vacuum. Such electrons are one type of non-thermalized electrons, generally referred to as 'hot' electrons. Their ability to cross the depletion layer without thermalizing in that region, in contrast to the situation

in the flat-band region, results from the existence of a narrow depletion layer (<200 Å) and the associated large electric field.

Photoemission into a vacuum is irreversible because of the infinity of states in free space. Photoemission from a metal into a vacuum can be obtained from the above analysis by taking the limit $E_g \rightarrow 0$, where E_g is the band-gap.

Photoemission from a semiconductor into another phase of condensed matter is a valid concept if the electron emission is into continuum states, that is, into the conduction band, for example, of an aqueous electrolyte. The efficiency of emission is limited by differences in effective momentum k and mass m^* of the two phases. The concept can be generalized to include positive hole photoemission from the semiconductor into a continuum of hole states. These processes are illustrated in Fig. 3 for photons labelled $h\nu_{PE}$. The band edges and energy gap for the aqueous electrolyte are based on the model for liquid water as a large gap, lone-pair, amorphous semiconductor³. Figure 3 shows the effects of a space charge arising from the inequality of the work functions of semiconductor and electrolyte, $W_{sc} \neq W_{c1}$. For the p-type semiconductor, $W_{c1} < W_{sc}$; for the n-type semiconductor, $W_{c1} > W_{sc}$. These are the usual cases since $W_{sc} \approx W_{sc}^p + E_g$.

Electron or hole emission involves interchange between kinetic and potential energy; only total energy remains constant during the emission processes shown in Figs 1-3. The total energy for each electron divides as follows: the energy from the Fermi level, E_f , up to E_c is potential energy; from E_c to the eigenvalue E it is kinetic energy. Thermodynamically, the energy

Quantum well: An effective potential well created by a minimum in the conduction band or a maximum in the valence band that arises when a smaller band-gap semiconductor is sandwiched between a larger band-gap semiconductor. When the physical dimensions of the sandwich layers become small (comparable to the mean free path of electrons or holes), conduction electrons and positive valence band holes are localized in a dimension perpendicular to the layers because of quantization of the energy states in the well.

Quasi-Fermi level: The energy level for which the occupational probability for an electronic particle is one-half under steady-state conditions (time-independent but non-equilibrium). The quasi-Fermi levels for electrons and positive holes are different because of non-equilibrium concentrations of injected electronic particles, either electrons and/or holes.

Redox couple/redox potential: A redox couple is a pair of electron donor and acceptor species in solution that define a potential for charge transfer. At equal concentrations of donor and acceptor species (called the reduced and oxidized forms of the couple), the thermodynamic driving force for electron transfer to the acceptor or from the donor are equal. The couple is in equilibrium and this condition defines the standard redox potential, E_{redox}^0 , which is the electrochemical potential in the liquid electrolyte. The potential at other concentrations is related to E_{redox}^0 through the Nernst equation.

Solvated electron: A conduction electron in an electrolyte polarizes nearby molecules so that in this region the structure of the electrolyte is deformed and the electron acquires close ligands, that is, it is solvated. The solvated electron is, in fact, a polaron of rather large mass.

Space charge: The double layer of charge produced near the surface of a semiconductor in contact with a second phase resulting from the initial inequality of electrochemical potentials (that is, work function, redox potential, Fermi level) for the two phases. The charge is generally distributed over finite dimensions in the semiconductor.

Thermalized carriers: Electrons or positive holes that are in thermal equilibrium with the lattice, and move in semiconductors near the band edges E_c and E_v .

Work function: Work required to remove an electron from the Fermi level of a condensed phase into vacuum with the electron having zero kinetic energy. For liquid electrolytes the work function is identified with the redox potential of the electrolyte.

Zero-phonon transition: Optical transition between electronic states in which phonons are neither created nor annihilated. The transition normally occurs from the zero-point vibrational level of the initial state to that of the final state.

available to do useful work depends on an electron occupancy of state E in excess of thermal occupancies at the lattice temperature, and on $E - E_f$; the total available energy is independent of division into kinetic and potential energy. Similar considerations apply to the positive holes. With applied voltage and/or photoexcitation, E_f may for some conditions be described as split into two quasi-Fermi levels for electron and positive hole, E_f^e and E_f^h , respectively. The concept of quasi-Fermi levels is valid if occupancies of electron and hole states are separately in accordance with Fermi statistics.

Photoemission from the semiconductor into the forbidden gap, E_g^{el} , of the electrolyte modelled as an intrinsic semiconductor (undoped and free of defects) is obviated by the absence of allowed states within E_g^{el} . Here the electronic wavefunction ϕ attenuates exponentially in the electrolyte with a mean distance $\hbar/\sqrt{2m|E'|}$, where E' is measured from the band edge. Thus photoemission with electron energies within E_g^{el} can occur only within a range of a few molecular distances.

A more complete model of an aqueous electrolyte takes account of band tailing: that is, the allowed eigenstates tail into the forbidden gap. This shows itself in the exponential tail of the optical absorption of amorphous semiconductors and is evident in the vacuum ultraviolet absorption of water³. In general, band tailing can be explained in terms of the microfields generated by departures from a perfect periodic potential so that sharp E_c and E_v no longer exist⁴, or, alternatively, in terms of band edges which undulate spatially because of compositional and/or structural inhomogeneities⁵. Thus photoemission into

Fig. 2 Hot electron emission into vacuum resulting from band bending in negative electron affinity photocathode. Energy distribution of emitted electrons is shown (from ref. 2).

the band tails is predicted but with lower probability because of the low densities of states.

Another mechanism specific to liquid electrolytes is photoemission directly into solvated electron states⁶. This depends on the molecular polarization and orientation in the vicinity of the trapped electron. The lowest of these states in water lies about 2 eV below the unsolvated electron states. The solvated electron is a low mobility polaron, a quasi-particle well known in the solid state. Because electron emission is fast compared to intermolecular motion, photoemission directly into solvated electron states depends on the electrolyte preparing itself spontaneously in a state of polarization consistent with the solvated state. Since liquid electrolytes are at equilibrium, the probability of such pre-transfer polarization into states 2 eV below the band edge is quite unlikely. Similar considerations apply to the possibilities for photoemission into self-trapped positive hole states of the electrolyte.

Photoinduced charge transfer

Photoinduced charge transfer (PCT) is the process wherein electron-hole pairs are first created in the conduction and valence bands of semiconductor electrodes by absorption of photons with band-gap energies; then separated by the field in a depletion layer at the semiconductor-electrolyte interface; finally electrons or holes are injected into the electrolyte to drive redox reactions. For n-type semiconductors, the holes move to the semiconductor-electrolyte interface to generate an oxidation reaction (semiconductor is a photoanode); for p-type semiconductors, electrons move there to generate a reduction reaction (semiconductor is a photocathode). Photoinduced electron transfer is illustrated in Fig. 3a and hole transfer in Fig. 3b for photons labeled $h\nu_{\text{PCT}}$: PCT can occur from carriers with energies near the band edges in contrast to the energy required for photoemission. In addition, under certain conditions, fast PCT by direct injection into dopant or defect states of the electrolyte may be possible. Processes involving PCT have been extensively studied in recent years, and many reviews are available⁷⁻¹⁰.

The impetus for this research is the potential application of liquid junction devices to solar energy conversion⁷⁻¹⁰. Photoelectrochemical cells containing photoactive semiconductor electrodes can be used either to drive redox reactions (for example, water splitting, CO_2 reduction, and N_2 reduction) producing fuels and chemicals, or in electrochemical photovoltaic cells to produce electricity.

The important distinction between PCT and photoemission is that in the latter the photogenerated electrons or holes are injected into the continuum states of the electrolyte, whereas in PCT the photogenerated carriers are injected into dopant or defect states that exist in the band-gap of the electrolyte. Dopant states are associated with the redox potential of redox couples added to the liquid, whereas defect states are redox potentials associated with the liquid itself. The latter are the native defects of the liquid electrolyte; for example, H^+ and OH^- ions in liquid

Fig. 3 Photoemission and photoinduced charge transfer (PCT) processes from semiconductors into liquid electrolytes: *a*, for electrons; *b*, for holes. Photoemission occurs with $h\nu_{PE}$; PCT occurs with $h\nu_{PCT}$. The PCT processes are shown for Type I and Type II hot carrier injection. Thermalized PCT processes inject the carriers from the bottom of the semiconductor conduction (or valence) band at the semiconductor-liquid interface. The energy distribution of the electron acceptor in the electrolyte is shown, and arises from fluctuations of the solvation shell around the acceptor (see Fig. 4 for further details).

water. Thus, the distinction is based primarily on the nature of the relevant electronic states of the electrolyte, rather than on intrinsic differences in the nature of the photoprocesses in the semiconductor. This is evident in Fig. 3.

In PCT, the carriers injected into the electrolyte can either be fully thermalized in the semiconductor or not. When thermalized, the photogenerated electrons and holes arrive at the interface with energies corresponding to the band edges E_c and E_v at the surface, respectively. These carriers always remain in equilibrium with the lattice through electron-phonon interactions, and dissipate the kinetic energy created by band-bending in the depletion layer as heat, as the carriers traverse the depletion layer. In thermalized PCT, only redox potentials that lie within E_g of the semiconductor at the interface are accessible to the injected charge.

For the case of non-thermalized PCT, illustrated in Fig. 3, the photogenerated carriers are injected into the electrolyte before they have undergone complete thermalization as they move from bulk semiconductor into the electrolyte. This process, called hot carrier injection, has been analysed in some detail¹¹⁻¹⁴, and is discussed further below. For hot carrier injection, redox couples that have potentials outside E_g of the semiconductor at the liquid contact are accessible.

Finally, we discuss the role of surface states. In semiconductor-vacuum and semiconductor-solid interfaces, the major effect of surface states is to pin the Fermi level so that the band-bending is independent of, or insensitive to, the nature of the second phase contacting the semiconductor. In semiconductor-liquid interfaces, the nature and effects of surface states can be quantitatively and qualitatively different from those of solid state junctions. First, ionic species in the electrolyte can be specifically

Fig. 4 *a*, Adiabatic potentials for ground (reduced) and ionized (oxidized) states of dopants in polar semiconductors, insulators or electrolytes, with Franck-Condon and zero-phonon transitions. *b*, Probability distributions for radiative transitions. *c*, Electronic energy levels, with thermodynamic dopant level E_t and effective densities for transitions. For redox couples in electrolytes E_t is identified with E_{redox}^0 (see box).

adsorbed onto the semiconductor either to passivate surface states or create new ones¹⁵. Second, Fermi level pinning or surface state charging under illumination can move the relative energy levels of the semiconductor with respect to those of the liquid electrolyte, and hence affect the kinetics of charge transfer¹⁶⁻¹⁸. Finally, surface states can mediate the charge transfer such that it occurs from the surface state rather than from the semiconductor band edges²⁰; this could also have a very large effect on the kinetics of PCT.

Large-gap amorphous semiconductors

Liquid electrolytes such as water can be described, with respect to electronic states, as large-gap amorphous semiconductors. The optical properties of pure and doped liquid water have been explained with this model³. It also provides the basis for interrelating some electrochemical concepts (for example, redox couples) with semiconductor concepts (for example, donor and acceptor dopants). However, semiconductor theoretical analyses of electrolyte-semiconductor junctions require modification to take account of the large density of mobile ions in liquid electrolytes.

Charged point defects in crystalline semiconductors or insulators are well known to have bound states for electronic particles: bound electron states for a positively-charged defect and bound hole states for a negatively-charged defect—termed donor and acceptor dopants²¹ respectively. Some uncharged dopants bind an electron or a positive hole and are referred to as isoelectronic dopants²².

These dopants in polar semiconductors or insulators have bound states whose energies are dependent on occupancy. This is a consequence of electron-phonon interaction and can be

visualized in detail by considering the adiabatic potentials $V(R)$ for two states of occupancy, as shown in Fig. 4a. $V(R)$ is the interaction potential between the atoms, in the region of the dopant with position coordinates $R_1, R_2, R_3, \dots$, symbolically represented by the single coordinate R , and is dependent on electronic state. Thus, the equilibrium value for R is different depending on whether or not an electronic particle is bound to the dopant. Optical attachment or detachment of the particle in accordance with the Franck-Condon principle (see standard texts, for example, ref. 23, and box) will be followed by lattice relaxation from the equilibrium position of the initial state to that of the final state.

The $V(R)$ are assumed harmonic with the same force constant for the ground and excited electronic states; the change in polarization energy is designated λ (anticipating identification with change in solvation energy for ions in electrolytes); $h\nu_0$ is the zero-phonon transition energy and equals E_i , which determines the thermodynamic occupancy of the two states; $h\nu_a$ and $h\nu_e$ are the Franck-Condon transitions for optical absorption (ionization) and emission (deionization), respectively. In Fig. 4b the probability distribution for these transitions is shown. Their band widths and Stokes shift are consequences of zero-point and thermal occupancy of the initial state, and of the transformation from the R -coordinate to transition energy.

These states and transitions can be approximately represented on an electronic energy level diagram as shown in Fig. 4a. We emphasize, as have others²⁴, the differences between $V(R)$ and electronic energy E . E_i lies at that energy below the conduction band edge E_c , with the approximation that E_c is independent of local polarization. For Franck-Condon transitions, the effective densities of states, $\rho(E)$, for ionization and de-ionization are respectively displaced, deeper and shallower by λ , and also broadened. The $\sqrt{E - E_c}$ dependence of $\rho(E)$ for the conduction band is also shown.

The same phenomena occur with redox couples in liquid electrolytes. The two states of occupancy correspond to reduced and oxidized forms of the couple, that is, dopant, similar to those shown in Fig. 4. The structure of the liquid does not have translational periodicity and therefore its lattice dynamics are not describable by phonons; however, the relaxation process is describable in terms of local modes and is basically the same as if the matrix for the dopant were crystalline. The $V(R)$ for each electronic state of occupancy or of excitation is characterized by different equilibrium molecular coordinates R , now in the solvation shell; λ is the energy associated with the reorganization of the solvent molecules around the redox species as it becomes oxidized or reduced. In general, the force constants are different but here are approximated as the same. The energy distributions of oxidized and reduced forms of a redox couple can be related respectively to those of ionized donor (or neutral acceptor) and those of neutral donor (or ionized acceptor) of point charged semiconductor dopants. However, the non-radiative charge transfer transitions for redox couples in electrolytes have different energy dependences than radiative charge transfer transitions for dopants in semiconductors if the former involve prior reorganization of the coordination shell: that is, if the transfer occurs adiabatically rather than vertically. This is, of course, basic to the Marcus theory²⁵. On the other hand, Franck-Condon effects have been effectively invoked by Gerischer²⁶ to describe charge transfer at metal-electrolyte and semiconductor-electrolyte junctions. Tunnelling of electrons or positive holes from electrolyte to semiconductor or metal in accordance with the Franck-Condon principle, that is with fixed atomic coordinates, will be at the energies and with the band widths of Fig. 4.

The transfer of electronic charge between a redox couple and an electrode involves only the states of the couple, not those of either free or solvated electrons, and thus the thermodynamic potential of the couple, E_i of Fig. 4c, will be at the Fermi level of the electrode. Ionic transport maintains continuity of current to the redox couple. This differs from charge transfer in semiconductors, for which Fermi levels are determined by conduction

and valence band edges, as well as by dopant states; these band states are necessary for current continuity because of the absence of significant ionic transport in most semiconductors. The explanation of this difference is that the dopants in liquid electrolytes are fully compensated by other dopants or by native defects. Thus conduction electrons or valence band holes are not present in normal electrochemical processes; they are unnecessary in view of the presence of mobile ions. In other words, for PCT the redox couple is decoupled from the band structure of the electrolyte, whereas the semiconductor dopant is not decoupled from the band structure of the semiconductor. However, for photoemission the relationship of the states of the redox couple to the band structure of the electrolyte is, of course, important; in this case the redox couple is not decoupled from the electrolyte band structure.

The difference between semiconductor-electrolyte junctions and semiconductor-semiconductor junctions is thus evident for PCT. For semiconductor-electrolyte junctions, electrons or positive holes can be injected into redox couples and continuity of current satisfied by ionic transport; for semiconductor-semiconductor junctions electron or positive hole injection from conduction or valence band states of one semiconductor into dopant states within the gap of the other semiconductor is obviated by the absence of continuity of current owing to the immobility of the dopants and the absence of inter-dopant charge transport. However, for photoemission the relationship of the states of the redox couple to the band structure of the electrolyte is, of course, important.

Finally, semiconductor-liquid electrolyte junctions involve space charge, in the electrolyte from accumulation or depletion of mobile ions, and in the semiconductor from electronic charge transport for equilibration¹⁴. The electrolyte is charge compensated so that its Fermi level lies near the middle of its energy gap. For moderate electrolyte concentrations, the mobile ions lead to a narrow space charge, that is, Helmholtz layer, similar, as regards high density of space charge, to a junction involving a semiconductor doped to degeneracy. Dilute electrolytes lead to a wider space charge analogous to low doped semiconductors.

Hot carrier photoinduced charge transfer

Mobile electronic particles are normally equilibrated with the lattice modes; thus, occupancy of the electronic states is characterized by the same temperature as that for occupancy of phonon levels. Exceptions occur under severe perturbations, for example, high electric fields, during which energy is acquired by the electronic particles faster than thermalization with the lattice occurs. In this way the energies of the electrons and/or holes increase and the particles are referred to as hot although their energy distribution may not in general be describable by a temperature. If the density of the carriers is high, that is, $\geq 10^{14} \text{ cm}^{-3}$, collisions among carriers are sufficiently frequent for the distribution to become maxwellian²⁷; otherwise the carrier distribution is non-maxwellian. A well-known example is the displaced maxwellian for an electron gas in an applied electric field, in which the normal velocity distribution is shifted for its velocity component in the direction of the field. Photogenerated hot carriers have, of course, initial distributions dependent on the spectrum of the photoexcitation: for example, with a monochromatic source and excitation limited to transitions with $\Delta k = 0$, the initial photo-electron and photo-hole distributions will each be a δ -function. For dilute electrons in intense electric fields, over distances less than the mean free path for phonon scattering, ballistic motion occurs. This phenomenon has been reported for short semiconductor devices²⁸.

The energy distributions of photogenerated conduction electrons and valence band holes, in the region of a semiconductor-electrolyte junction, depend on the photoexcitation spectrum, on intraband relaxation, on interband electron-hole recombination, on the rate of charge transfer from semiconductor to electrolyte, and on the dependence of that rate on electronic energy. The magnitudes of these rates have been estimated, with attention to the effects of quantization of electronic states in

narrow depletion layers on intraband relaxation^{11,13}, and hot carrier transfer predicted from states below the band edge of the bulk semiconductor but higher than thermal energy above the edge at the interface. These are defined as Type I hot carriers. Type II hot carriers are distinguished as having energies more than thermal energy above the band edge of the bulk semiconductor. These processes are illustrated in Fig. 3.

Transfer of photoexcited carriers across semiconductor-electrolyte interfaces have been analysed using the master equation¹³. The total current depends on charge transfer versus recombination. The energy distribution of the charge transferred depends, in addition, on relaxation, density of depletion layer states, and the energy 'window' through which transfer occurs to the redox couple. Back transfer is assumed negligible in this analysis.

Experimental evidence for Type I hot electron injection across illuminated semiconductor-electrolyte interfaces has been obtained for p-GaP (ref. 29) and p-InP (ref. 30) electrodes in non-aqueous electrolyte. In these experiments, reduction reactions of electron acceptor species having redox potentials above E_c at the surface are observed. Such reactions are called supra-band-edge redox reactions, and can only occur via a hot carrier process if the semiconductor band edges do not move with respect to the electrolyte redox levels, during the experiment. The absence of band-edge-movement was established through monitoring of the band-edge energies by capacitance measurements. For p-GaP, the electron acceptor was anthracene (0.9 eV above E_c), and for p-InP, the electron acceptor was p-nitrobenzonitrile (0.5 eV above E_c).

Quantization in small particles

Size quantization effects, previously discussed for narrow depletion layers in planar semiconductor-electrolyte junctions^{11,13}, and well established for semiconductor quantum wells^{31,32} are also evident for small semiconductor particles (20–200 Å diameter) suspended in electrolytes^{33–38}. For the latter, the conduction and valence bands are separately fully quantized in three dimensions into discrete states, and the effective band gap increased as the particle size becomes very small. This essentially produces a hot carrier effect in that the kinetic energy is increased by the confinement. The effect is dependent on effective mass, and is thus material dependent; size quantization effects appear with larger particle sizes for semiconductors with smaller electron effective mass. For the same material, the confinement effect is different for different extrema of the band structure³⁸; for example, the low effective mass Γ -conduction band minimum of tetrahedral semiconductors is perturbed more than the higher effective mass X- and L-band minima. For quite small particles of direct-gap tetrahedral semiconductors, size quantization perturbs the effective band edges into the non-parabolic region of the Γ minimum. For very small particles, for example, ~20 Å for CdS, degeneracy of the three conduction band minima is predicted³⁸.

In addition to the separate perturbations of the conduction and valence bands, small dimensions may result in correlation between the electron and positive hole when they are confined to the single particle. One consequence is that the internal energy of excitons created during photoexcitation increases as the confinement dimensions (D) become comparable to or less than the Bohr radius of bulk excitons (r_B), for example $D \leq r_B \approx 100$ Å for GaAs (refs 36–38). This effect is well established for laminar semiconductor quantum wells³⁹. For small semiconductor particles suspended in electrolytes, the effect of correlation on the band structure itself also becomes appreciable as a result of the electron and hole being confined to a single particle. The effects of correlation on band structure and excitons both depend on occupancy of states, and are present or not depending on the details of the optical experiment; for photoexcitation, the accessible electronic states, whether originating from band or excitonic states, are affected by the Coulomb correlation of electron and hole; for photoemission or fast PCT, the accessible

states are, to a good approximation, band states quantized by confinement, but quite distinct from excitonic states.

In general, for semiconductors with low effective mass electrons, the confinement perturbation is greater than the Coulomb correlation. Thus, for photoexcitation, photoemission or PCT the general features of bulk band structure are predicted to survive in quite small particles, with the forbidden gap increased.

Some of these and related effects have already been found experimentally, for example, the predicted blue shift in absorption spectra^{33,36,37}. However, the distribution of particle sizes in currently available experimental samples gives rise to broad spectra, rather than the discrete spectra predicted theoretically for particles of uniform size and shape.

Size quantization effects with small semiconductor particles in electrolytes should lead to important modifications in the nature of charge transfer and the attainable power conversion efficiencies in photochemical devices: for example, shifts in effective photochemical redox potential have been predicted^{33–38}. Also, unusual kinetics are expected with photoexcitation of very small particles: for example, electron-hole recombination will occur in pairs (geminate recombination), with each pair confined to a particular particle, rather than by the second-order process of bulk semiconductors³⁸.

Conclusions

Photoelectron emission and photoinduced charge transfer at semiconductor-electrolyte junctions can be clearly distinguished. These junctions can be described by semiconductor heterojunction theory if modifications are made to include the effects of charge compensation and of the mobile ions in the electrolyte. Dopants in polar semiconductors and redox couples in electrolytes are similar as regards polarization changes on occupancy but differ as regards equilibration with band edges. Surface states can play an important role in semiconductor-electrolyte junctions in that in addition to the possibility of pinning the Fermi level as in solid state junctions, they may interact strongly with the electrolyte, cause band movement with respect to the electrolyte redox potential, and mediate charge transfer to the electrolyte. Hot electrons were predicted theoretically and found experimentally. Two types of hot carriers can be distinguished on the basis of their electronic kinetic energies in depletion layers and in the semiconductor bulk, respectively. Quantization effects can occur in narrow depletion layers and in small semiconductor particles. This can cause major changes in optical properties and charge transport.

Detection of a radio emission at 3 kHz in the outer heliosphere

W. S. Kurth*, D. A. Gurnett*, F. L. Scarf† & R. L. Poynter‡

A radio source in the outer heliosphere has been detected by the plasma wave receivers on Voyagers 1 and 2. The radio emission is observed in the frequency range 2-3 kHz, and is above the local solar wind electron plasma frequency whenever supporting plasma density data are available. The maximum spectral density of the emission recorded is $\sim 10^{-14} \text{ V}^2 \text{ m}^{-2} \text{ Hz}^{-1}$. The bandwidth of the radio noise is $\sim 1 \text{ kHz}$. Possible sources include continuum radiation from Jupiter's distant magnetotail and radiation at the second harmonic of the plasma frequency at the heliopause. If the latter interpretation is correct, these data represent the first remote observations of the heliopause.

THE Voyager 1 and 2 spacecraft are currently sampling the interplanetary environment at heliocentric radial distances of 19 and 13 AU, respectively. Since the Saturn encounters in 1980 and 1981, the plasma wave data have shown very little activity in the outer heliosphere. The primary waves observed include occasional electron plasma oscillations and ion-acoustic waves, sometimes detected in association with interplanetary shocks. Figure 1b shows the trajectories of Jupiter, Saturn, Uranus and Voyagers 1 and 2 for the interval 30 August 1983 to 21 February 1984; during this time a radio emission near 3 kHz was being detected by the plasma wave instruments on both Voyagers. Figure 1a shows a meridional view of the outer planets and the trajectories of the two Voyagers. In this view, the abscissa is in the ecliptic plane and the positions of the various planets and spacecraft have all been rotated into the same plane.

The observations discussed here were obtained on both Voyager spacecraft using identical plasma wave receivers which measure the electric field component of plasma and radio waves in the frequency range 10 Hz to 56 kHz by the use of 16-channel spectrum analysers and wideband receivers with passbands of 40 Hz to 12 kHz (ref. 1).

Observations

During the period from 30 August 1983 to the present, a very weak signal has been apparent in the 3.11-kHz channel of the Voyager 1 plasma wave instrument. The 3.11-kHz data for a 6-month interval are plotted as a function of time in Fig. 2. Each point in Fig. 2 represents a 51.2-min average of the electric field spectral density in the 3.11-kHz channel. It is apparent that after about day 242 (30 August) 1983 a smoothly varying signal was continuously present. Amplitude variations within the 51.2-min averaging intervals were small compared with the long-term variations seen in Fig. 2. Beginning at about day 292, the variations appear to be quasi-periodic with a period of about 26 days. This is close to the sidereal period of the Sun, hence, we suspect the solar wind may be responsible, in part, for the amplitude variations. There also seems to be a gradual overall variation in the amplitude of the emission with a rise from the onset near day 242 to the peak near day 285 and a subsequent

Fig. 1 The trajectories of Jupiter, Saturn, Uranus, and Voyagers 1 and 2 during the interval 30 August 1983 to 21 February 1984 when the Voyager 1 plasma wave receiver was detecting a new radio emission in the frequency range 2-3 kHz. Evidence from Voyager 2 indicates the radio emission may have been observable from that vantage point over a similar interval. *a*, The positions of the outer planets and the Voyager spacecraft rotated into a single meridian plane with the ρ -axis lying in the ecliptic plane. *b*, The projection of the trajectories of the same bodies in the ecliptic plane with the x -axis pointing in the direction of the first point in Aries, γ .

Fig. 2 Electric field spectral densities from the Voyager 1 3.11-kHz plasma wave receiver channel plotted as a function of time for slightly more than six months. Each point represents a 51.2-min average. The radio emission first appeared on day 243 1983.

decrease in amplitude towards the end of the plotted interval. During this entire time interval, no signal was detected in the 5.62-kHz channel. For a few one- or two-week periods a much weaker emission could be seen in the 1.78-kHz channel.

Several times during the interval plotted in Fig. 2, the wideband channel of the Voyager 1 plasma wave receiver was interrogated. For each wideband interrogation, four contiguous 48-s 'frames' of plasma wave data with high temporal and spectral resolution were obtained. In each wideband frame transmitted after day 242 1983, a weak band of emission near 3 kHz could be seen. Table 1 summarizes the wideband observations of the 3-kHz emission by both Voyager spacecraft. SCET is the spacecraft event time for each wideband observation and f_0 and $f_{\min}$ are the frequencies of the peak of the emission and the low-frequency cutoff, respectively. The electron plasma frequency as determined by the Plasma Science instrument (J. W. Belcher, personal communication) is labelled f_p .

An example of one of the wideband frames is shown in Fig. 3 in the format of a frequency-time spectrogram where the amplitudes of waves are plotted as a function of frequency and time. The most intense waves are black. In Fig. 3, the intense tones at frequencies below 1 kHz are interference from the operation of the onboard tape recorder used to record the wideband data. The very narrow tones at 2.4 and 4.8 kHz are the first and second harmonics of the spacecraft power supply.

The diffuse noise seen between 2 and 3 kHz is the emission which accounts for the signal received in the 3.11-kHz channel plotted in Fig. 2. This spectrogram is typical of the others received since day 242 1983, except for variations in the signal strength and minor variations in the lower frequency cutoff of the emission. The data from a 4-s interval in the spectrogram in Fig. 3 were averaged to form the spectrum shown in Fig. 4a which illustrates the detailed structure of the emission band. The power supply interference tone at 2.4 kHz, which rises out of the middle of the emission band, and a notch filter which serves to limit the power supply interference, cause some difficulty in the interpretation of the spectrum in Fig. 4. The gap

Fig. 3 Spectrogram showing the intensity of waves as a function of frequency and time for a 20-s interval. The diffuse emission seen between 2 and 3.5 kHz is the new radio emission reported here. The narrowband tones at 2.4 and 4.8 kHz as well as below about 800 Hz are spacecraft interference. Start time 2021: 52 SCET of day 307, 1983; $R = 17.9$ AU; celestial lat. = 25.5° .

in the spectrum at 2.4 kHz may be due to the notch filter, but we cannot rule out the possibility of a complex spectral structure which is inherent in the radio emission itself.

The Voyager 2 3.11-kHz channel sensitivity is not as great as that on Voyager 1 because of a partial failure in the Voyager 2 Flight Data System which occurred shortly after launch. Hence, at these low wave amplitudes we do not see any response in the Voyager 2 spectrum analyser channels. On the other hand, wideband frames obtained from Voyager 2 (which are unaffected by the Flight Data System failure) show a feature which is very similar to that shown in Fig. 3 (see Table 1). The earliest Voyager 2 wideband frame showing evidence of the emission was obtained on day 257 (14 September) 1983 when the spacecraft was 12.7 AU from the Sun. Samples showing evidence of the emission were also obtained on days 294, 307, and 339 of 1983 and day 3 of 1984. Because no wideband frames were obtained on Voyager 2 between day 228 (when the emission was not seen in the wideband data) and day 257, it is possible that the signal has been continuously present at Voyager 2 since about day 243 as was the case for Voyager 1. This close correspondence in onset times observed at two locations separated by nearly 10 AU suggests the two spacecraft are detecting a temporal change as opposed to a spatial variation.

Figure 4b shows a spectrum taken on day 307 by the Voyager 2 plasma wave instrument. The receiver threshold is not quite as low as in the case of Voyager 1, but the similarity between the emission just below 3 kHz with the feature shown in Fig. 4a can be readily seen. Note that the amplitude of the emission is nearly identical to the emission observed by Voyager 1.

The Voyager 2 observations of the emission are important in our identification of the emission as a radio signal because the plasma instrument² on Voyager 2 can provide a measure of the local electron density, hence, plasma frequency. (The Voyager 1 plasma instrument has not functioned since shortly after the Saturn encounter.) If the emission is a freely propagating radio emission, then it must lie above both the electron plasma frequency and gyrofrequency. For four of the five days when wideband data are available, a determination of the density from the plasma instrument yielded values ranging from 0.02 to 0.04 cm^{-3} as shown in Table 1 (J. W. Belcher, personal communication). The respective plasma frequencies range from

Fig. 4 *a*, 4-s average spectrum taken from the spectrogram shown in Fig. 3 at 2021: 56 SCET. The shaded portion of the spectrum corresponds to the new emission. Note that the interpretation of the spectrum is complicated by the existence of a notch filter and power supply tone centred at 2.4 kHz. *b*, A 4-s average spectrum of the 3-kHz radio emission observed by Voyager 2 at a time (1632: 05 SCET) very close to when the emission shown in *a* was observed by Voyager 1. Note the similar amplitude of the features near 3 kHz in *a* and *b*.

1.3 kHz to ~ 1.8 kHz because $f_p(\text{Hz}) = 8,980\sqrt{n_e}$, where n_e is the electron density in cm^{-3} . For days 257, 307, and 339, the values for f_p are obtained from the 3-min determination of n_e made closest to the wideband frames and have errors of $\sim 10\%$. No reliable measurement is available for day 284 and the value for day 3 of 1984 is a daily average used in the absence of detailed analyses which are not yet completed. The low-frequency cutoff of the emission ranged from ~ 2 to nearly 3 kHz over the five intervals of wideband data. In each case, the emission exhibited a low-frequency cutoff which was well above the local electron plasma frequency. As the emission lies above f_p and the electron gyrofrequency in the solar wind is much less than f_p , the emission meets a necessary condition for being a freely propagating radio wave. It is easy to speculate that the periodic dips in the emission amplitude seen in the Voyager 1 data plotted in Fig. 2 are due to the passage of relatively high-density structures in the solar wind associated with high-speed streams which shield the spacecraft from the source of emission.

With the available data, it is not possible to confirm that the emission is a freely propagating radio wave; however, we can eliminate local plasma phenomena with a high level of confidence. There are two types of local (non-propagating) phenomena which have been observed at, or above, the local plasma frequency in the solar wind. The most familiar waves in this frequency regime are electron plasma oscillations or Langmuir waves. The observed waves are almost certainly not plasma oscillations as the bandwidth of the observed emission is much larger than that for plasma oscillations, particularly at low amplitudes and plasma oscillations are characterized by a very sporadic temporal character. The observed emission shows only very smooth variations in amplitude with time.

The second type of local phenomena which might be considered are quasi-thermal electrostatic plasma waves⁷. Hoang *et al.*³ discuss the spectral form of the thermal plasma emission in detail for both long and short (compared with the Debye length) antennas. For the typical solar wind observed in this epoch by the two Voyagers, the density is 0.05 cm^{-3} , hence, even with a temperature as low as 1 eV, the Debye length is > 30 m, compared with an effective antenna length on the two Voyagers of 7 m. Therefore, the short antenna results of Hoang *et al.* are relevant to this discussion. The quasi-thermal plasma noise detected by a short antenna has a power law spectrum with an index of -1.5 and shows no peak and no cutoff at f_p . The spectra shown in Figs 3 and 4 exhibit both a low-frequency cutoff and at least one peak. These waves, therefore, are clearly not the thermal electrostatic waves discussed by Hoang *et al.*³.

Table 1 also shows that the frequency of the peak in the emission is nearly the same at both spacecraft despite the relatively large variations in local plasma conditions which would be expected between two points separated by ~ 10 AU. The nearly constant frequency would not be expected if the emission were a local effect. Finally, the fact that Voyagers 1 and 2 both began detecting the 3-kHz emission at about the same time despite being nearly 10 AU apart argues strongly for a freely

propagating radio emission and against a local plasma phenomenon.

Possible sources

Several possible sources exist in, and beyond, the outer heliosphere for the radio emission reported here. The emission is most reminiscent of continuum radiation trapped in Jupiter's distant magnetotail because it lies in a very similar frequency range. Figure 5 shows an example of the continuum radiation observed $2,019 R_J$ downstream from Jupiter⁴, where R_J is the radius of Jupiter. Given that the continuum radiation is confined to the tail cavity by the surrounding high-density solar wind close to Jupiter and also given the geometry of the observations presented in Fig. 1, it is clear that the emissions would have to propagate down the jovian tail to a point where the waves are at a frequency greater than the surrounding solar wind plasma frequency. Having reached this 'window' they could subsequently propagate freely and possibly escape in the direction of the Voyager spacecraft.

However, a comparison of the two spectra from the outer heliosphere in Fig. 4 with that in Fig. 5 taken in Jupiter's tail suggests that the two emissions have different sources. The spectrum of trapped continuum radiation varies as $f^{-\alpha}$ where α ranges between 3 and 6 (ref. 5). The radiation in Fig. 4 clearly does not show that type of frequency dependence. Moreover, the other waveform samples from both Voyagers of the new radio emission do not deviate greatly from the form shown in Fig. 4. Hence, to identify the spectra in Fig. 4 with jovian continuum radiation, one would have to rely on the solar wind medium to reshape the spectrum. The general consistency of

Fig. 5 A 4-s average spectrum of continuum radiation trapped in the jovian tail $2,019 R_J$ downstream from Jupiter (shaded portion) obtained by Voyager 2 on 1 February 1980 at 0016: 26 SCET. Notice that this emission is sharply peaked at lower frequencies in contrast to the emission shown in Fig. 4.

the recently obtained spectra is inconsistent with such a shaping process.

An analysis of the amplitude of the new emission also argues against a jovian source. If the continuum radiation escaping from the tail of Jupiter were to be emitted from some point along the tail (assumed to extend in the anti-solar direction from Jupiter), one would expect to see an approximate R^{-2} dependence in the intensity of the emission from the exit 'window'. From Fig. 1, we see that Voyager 1 and 2 are about 14.8 and 6.4 AU from the jovian tail axis, respectively; hence, one would expect a signal more than a factor of 5 times larger at Voyager 2 than at Voyager 1, but waveform samples taken on both spacecraft on 3 November (shown in Fig. 4) indicate that the spectral density at the peak of the emission band is nearly identical at both spacecraft. (We have used a calibration technique similar to that used by W.S.K. *et al.*⁵ which avoids the Voyager 2 calibration uncertainty.) Also, the intensity of the Voyager 1 spectrum obtained at 18 AU is only a factor of about 3 less than that obtained only 2,019 R_J (~ 1 AU) downstream from Jupiter. Hence, it seems difficult to understand the emission as jovian in origin on the basis of intensity.

We have also performed a power spectrum analysis on the data presented in Fig. 2 to look for variations near the rotation period of Jupiter since some of the radiation detected in the distant jovian tail shows amplitude fluctuations with a period of about 10 h (ref. 6). No periodicity near 10 h was detected.

Thus, while Jupiter initially seems a likely source for the emission on the basis of the frequency of the emission, the spectral shape, the lack of spatial variation in amplitude, and the lack of 10-h periodicities cast serious doubts on this interpretation. Below, we examine other possibilities for the source of the emission.

Continuum radiation trapped within Saturn's magnetosphere has also been detected⁵. Although the position of Voyager 1 might seem to be ideal to detect such saturnian radiation when one examines only the ecliptic plane projection in Fig. 1b, Fig. 1a shows that the spacecraft was actually 8 AU north of the ecliptic; hence, it is difficult to understand how any radiation from Saturn could propagate to either of the spacecraft. Moreover, as with Jupiter, the saturnian continuum radiation spectrum does not match the spectra in Fig. 4. In addition, the saturnian radiation is even weaker than Jupiter's, thus, we conclude that Saturn is not a likely source for the newly detected radio emission.

Uranus is another possible source for the radiation as we do not know what radio emissions from Uranus might look like. Using observations of the Earth, Jupiter, and Saturn as guides, the upstream planetary radio emission which most closely resembles the new emission is escaping continuum radiation from the Earth^{7,8} and Jupiter⁹. The escaping continuum radiation from those planets is extremely weak, however, and even if Uranus had similar emissions, they could not be detected by either Voyager spacecraft at their present distances unless the source was extremely bright. Other types of planetary radio emissions are intrinsically more intense than the continuum radiation; their dynamic spectra, however, are more highly structured than the emissions reported here. Nevertheless, we cannot rule out Uranus as a source of the radio noise reported above until the Voyager 2 encounter with that planet in 1986, although, we now feel that Uranus is not a likely source.

It is possible that the new radio emission detected by Voyagers 1 and 2 is generated outside the heliosphere. With our lack of information about the region, particularly at such low frequencies, any number of sources might be contemplated. Once such source is a fast pulsar which might emit enough energy at low harmonics of its pulsing rate to be detected in the frequency range of a few kHz. However, we suggest that the broad bandwidth of the newly detected signal is sufficient to rule out pulsars as the source. In addition, the power flux of the band shown in Fig. 4a integrated over the 1-kHz bandwidth is of the order of 10^{-14} W m⁻². The radio luminosity of the Crab Nebula integrated over a bandwidth of 10^8 – 10^9 Hz is about 10^{31} erg s⁻¹

(ref. 10), hence, at a distance of ~ 1 kpc this corresponds to 10^{-16} W m⁻², much less than the value observed by the Voyager spacecraft. (An equivalent, but alternate comparison, is to calculate the power spectral density from the Crab assuming the 10^{31} erg s⁻¹ is emitted in a 1-kHz bandwidth. This would be about 10^{-19} W m⁻² Hz⁻¹ compared with a value of 10^{-17} W m⁻² Hz⁻¹ observed by Voyager.) It is interesting to think of what other sources of radio noise lie beyond the Solar System, but perhaps fruitless to speculate on them at this point.

We have considered one other possibility for the source of the radio emission: the heliopause, itself. It is reasonable to assume that there is a supersonic shock marking the heliopause (sometimes referred to as the terminal shock) and shocks are known to be the source of weak, relatively narrowbanded radio noise. Specifically, Dunckel¹¹, Gurnett¹² and Hoang *et al.*¹³ have all reported radio emissions at $2f_p$ emanating from the vicinity of the Earth's bow shock and a similar phenomenon has been reported near an interplanetary shock⁴. Theories for the emission at $2f_p$ have been offered by Fung *et al.*¹⁴ and Cairns and Melrose¹⁵. The fact that this type of emission is quite weak is countered by the large source size of the heliopause and resulting large solid angle as seen by an observer in the outer heliosphere. The smoothly varying temporal character and bandwidth of the new emission are consistent with the $2f_p$ model.

If, indeed, the heliopause is generating the radio emission at $2f_p$, some interesting statements can be made concerning the size of the heliosphere. This scenario implies that the plasma frequency at the heliopause is half of 3 kHz, or 1.5 kHz; n_e at the heliopause is then ~ 0.03 cm⁻³. One can expect a maximum jump in the density at the shock of a factor of 4 (and we also assume the interstellar density is higher than just inside the heliopause), meaning the density just inside the heliopause could be as low as 0.008 cm⁻³. This corresponds to a plasma frequency of about 780 Hz. Because the density in the solar wind falls as $1/R^2$ (assuming constant solar wind speed) and the plasma frequency is proportional to $\sqrt{n_e}$, the plasma frequency varies as $1/R$. Given that f_p is ~ 2 kHz at 18 AU (using Fig. 3) and that it drops to 780 Hz at the heliopause, it is easy to solve for the radial distance of the heliopause, that is ~ 46 AU.

Obviously, the reasoning above assumes no variations in the solar wind density as a function of time and is subject to several simplifying assumptions. Also, if one assumes the density in the interstellar medium is less than just inside the heliopause, the minimum f_p in the heliosphere is 1.5 kHz and Voyager 1 is very close to that point. Taking the value of 46 AU (with liberal error bars), however, we can compare it with other predictions of the distance to the heliopause. One popular method is to interpret the cosmic ray gradient to arrive at a distance to the boundary. One such prediction of >65 AU by Webber and Lockwood¹⁶ was based primarily on Pioneer 10 observations. As Voyager 1 is travelling more or less antiparallel to the interstellar wind flow and Pioneer 10 is headed in nearly the opposite direction, it is commonly assumed that the heliopause will be encountered at smaller heliocentric radial distances by Voyager 1, hence, 46 AU does not seem to be unreasonable. Voyager 1 will be at a distance of about 46 AU in 1991 and perhaps only then will we be certain of the source of this new radio emission.

Conclusion

Voyager 1 and 2 observations of a very weak signal in the range 2–3 kHz in the outer heliosphere at distances of 13–19 AU appear to be evidence of a newly discovered radio emission. While the frequency of the radio emission is similar to continuum radiation in the distant jovian tail, other observations are inconsistent with Jupiter as a source. One other possible candidate for the emission source is $2f_p$ radiation from the heliopause. This is a most exciting possibility, because if this is the case, these observations are our first glimpse of the edge of the heliosphere.

We thank J. W. Belcher for information on the electron density observed by the Voyager 2 plasma instrument during some of the events used in this study. We also acknowledge the program-

ming support of L. J. Granroth. Research at The University of Iowa was supported by NASA through contract 954013 with the Jet Propulsion Laboratory and grant NAGW-386 with NASA Headquarters. Research at TRW was supported by NASA

through contract 954012 with the Jet Propulsion Laboratory. The research described above was performed in part at the Jet Propulsion Laboratory, California Institute of Technology and was jointly sponsored by The University of Iowa and NASA.

A third type of murine T-cell receptor gene

Yueh-hsiu Chien, Daniel M. Becker, Tullia Lindsten, Maki Okamura, David I. Cohen* & Mark M. Davis

Department of Medical Microbiology, Stanford University School of Medicine, Stanford, California 94305, USA

By subtractive cDNA hybridizations, we have isolated a new species of T-cell receptor cDNA clone whose predicted amino acid sequence has homology to variable, constant, joining and diversity segments of immunoglobulins and T-cell receptors. The corresponding genomic sequence is also rearranged in several T-cell DNAs. The four potential N-linked glycosylation sites, frequency of expression and predicted molecular weight (27,800) of this molecule make it a likely candidate for the α -chain of the T-cell receptor. Expression data also indicate that this gene may be activated at a later stage of T-cell differentiation than the β -chain.

RECOGNITION of foreign entities by T cells is strikingly similar to that of B cells in the large number of specificities that are engendered and in the fixation in particular cell lineages of these specificities (reviewed in ref. 1). Unlike the mediators of B-cell recognition (immunoglobulins), however, T-cell receptors seem able to 'recognize' antigen only in conjunction with self-major histocompatibility complex (MHC) determinants. Cytotoxic T cells (T_c) typically require class I antigenic determinants ($H-2$)²⁻⁴ and helper T cells (T_H) require class II (Ia) determinants⁵. The affinity for self-MHC seems to be 'learned' in some way in the thymus^{6,7} before exposure to antigen and apparently allows T cells to focus on abnormalities of the organism's own cells. In addition, helper T cells up-regulate and suppressor T cells down-regulate B cells and other immune system-related responses.

Uncertainties concerning the biochemical and genetic nature of the T-cell receptor molecule(s) has been a major stumbling block in understanding the phenomena described above. Continual progress, especially in the past few years, has begun to provide some answers. In particular, T-cell cloning methodologies using either long-term lines or hybridomas¹ have allowed a better definition of the antigen-MHC reaction phenomena and have also provided large quantities of homogeneous cell populations of a single, defined specificity. This has also led to the development of clone-specific (anti-idiotypic) antisera⁸ and monoclonal antibodies⁹⁻¹³ which can either block or stimulate the response of the target cells to antigen¹⁰⁻¹³. These 'clonotypic' monoclonal antibodies were used successfully to precipitate the putative T-cell receptor molecule itself, an 80,000-90,000 dalton molecular weight (80-90K) sulphhydryl-linked heterodimer⁹⁻¹³ which on reduction yields α - and β -subunits of 40-50K each. These subunits seem to have both variable and constant fragments in tryptic peptide maps^{14,15}. Recently, cDNA clones encoding one chain of the T-cell receptor were isolated in mouse^{16,17} and man¹⁸. N-terminal

amino acid sequencing established that these clones encode the β -chain¹⁹ of the T-cell receptor heterodimer. The β -chain cDNA clones encode a 32K protein having variable, constant and joining (J) region elements remarkably similar to those of immunoglobulins^{17,18}. More recently, D (diversity) elements have also been shown to play a part²⁰⁻²³ in the formation of the

Fig. 1 cDNA subtractions and screening strategy. Calf thymus DNA was used to synthesize randomly primed ³²P-labelled cDNA by standard procedures⁴⁷ from poly(A)⁺ cytoplasmic 2B4 mRNA. The cDNA was initially 700 nucleotides (nt) average length and was allowed to fragment by autoradiolysis to ~300 nt long over a 2-week period. The subtractive hybridization was carried out by procedures described previously⁴². The ³²P-cDNA was first hybridized and hydroxyapatite-selected with the T_H hybridoma C10 mRNA, then with the T_H -like lymphoma line, EL-4. The twice-subtracted probe was then hybridized to a filter of 2B4 cDNA library in the vector λ gt10 as described elsewhere²⁰. Approximately 20,000 plaques were screened. Seven positive plaques were picked and rescreened with a probe of oligo(dT)-primed cDNA made of membrane-bound polysomal mRNA from 2B4, subtracted with mRNA from the P388D₁ macrophage line (MBT₁-Mac).

* Present address: Laboratory of Immunology, NIAID, National Institutes of Health, Bethesda, Maryland 20205, USA.

variable-region exon of this gene. The mechanism of rearrangement seems very similar to that of immunoglobulins²⁰⁻²², the only major difference being the extreme diversity and apparently accelerated rate of divergence of the different variable regions, apparently due to the presence of additional hypervariable regions in the molecule²⁴. These data have helped to elucidate the problem of diversity and clonal fixation of specificities by direct analogy with immunoglobulin.

The other questions specific to T-cell recognition are more difficult and require knowledge (and possession) of the gene encoding the second chain of the heterodimer (α). An apparent

Fig. 2 T cell-specific expression of TT11. The TT11 cDNA clone was labelled by nick-translation⁴⁵ and hybridized to a Northern blot⁴⁵ containing a panel of mRNAs as follows: *a*, Bal 17, B-cell lymphoma; *b*, M104E, plasmacytoma; *c*, 3T3, fibroblast line; *d*, P388D₁, macrophage line; *e*, 2B4; *f*, EL-4; *g*, BW5147. All are poly(A)⁺ cytoplasmic RNAs prepared by standard procedures⁴⁵.

answer in this regard was obtained by Saito *et al.*²⁵, who used subtractive cDNA selection methodologies¹⁶ to obtain a second immunoglobulin-like, T cell-specific cDNA clone (HDS4 and related species) which is rearranged in T_c DNAs and has elements homologous to variable, constant and *J* regions. Although this gene may encode one of the chains of the T-cell receptor for murine cytotoxic T cells, it seems unlikely that it also encodes the α -chain for the murine helper T cells for the following reasons: (1) there are no N-linked glycosylation sites (N-X-S) in the amino acid sequences predicted for the HDS4 series

clones, whereas three N-linked additions have been found in α -chains from three different murine helper T-cell lines²⁶⁻²⁸, including 2B4 (ref. 26), the subject of this report. (2) The HDS4 gene is not expressed in many T_H-cell lines (our results and S. Tonegawa, personal communication). That T_H and T_c cells use the same β -chain locus has been established^{25,29-31} by molecular genetic analysis. (3) A consistently low level of expression has been seen for this gene with respect to β -chains, that is, 1% of the level of β -chain expression in thymus and 2% of the level in spleen cDNA libraries (this paper), and $\leq 10\%$ of the β -chain level in some T_c-cell libraries (Z. Eshhar, personal communication). Although differences in translational efficiency or stability are possible, all known multi-chain molecules have mRNA species present in approximately equal amounts (see below).

In view of these questions, we generated a new cDNA probe designed to detect variable regions which might differ between various T-cell lines, and used this to screen a T_H cDNA library from the cytochrome *c*-specific hybridoma, 2B4 (ref. 12). One of the cDNA clones obtained in the screen, TT11, appears to encode a protein with many of the expected features of an α -chain and is expressed in both T_H and T_c cells. If this is confirmed to be the case, its characterization will identify the missing portion of the T-cell receptor molecule. However, this result also raises the interesting question of why there are three (or more) immunoglobulin-like chains in at least some T cells.

Isolation of cDNA clones

As peptide mapping has shown that the α -chains of the T-cell receptor molecules isolated from T_H cells are as diverse as the β -chains¹⁵, and given the distinct immunoglobulin-like structure of the β -chain of the T-cell receptor^{17,18} and the likelihood that the α -chain is encoded by a similar molecule, it seemed feasible to prepare a variable (*V*)-region-specific subtracted cDNA probe between T cells of differing specificities. This was achieved as shown in Fig. 1, where randomly primed, labelled cDNA⁴⁷ from the mRNA of the helper hybridoma, 2B4 (ref. 12), was synthesized; this probe was allowed to fragment by autoradiolysis to an average size of 300–400 nucleotides and then subtracted, first with C10 mRNA, then with EL-4 mRNA. The resultant probe should be enriched in 2B4 *V*-region-specific sequences, and was then used to screen a 2B4 cDNA library made in the vector λ gt10²⁰. The use of calf thymus DNA as a random primer gives fairly equal reverse transcription over the entire length of each mRNA species, thus eliminating the 3'-end bias of oligo(dT) priming. The size of 300–400 nucleotides is optimal in that it is large enough to give good reactivity in hybridizations,

Fig. 3 Rearrangement of the TT11 gene. Genomic DNAs from the livers of different mouse strains, various T-cell lines and hybrids of the B-cell lymphoma L10A, were digested with: *a*, HindIII; *b*, EcoRV; *c*, XbaI; *d*, BglII and electrophoresed through 0.7% agarose, blotted onto nitrocellulose and hybridized by standard methods⁴⁵ to a probe from the 5' half of TT11 (RI-RV; see Fig. 4). Arrows indicate altered bands, arrowheads indicate molecular weight markers. In the HindIII digest (*a*) the B10.A pattern is identical to that of the true parental, C57Bl/6.

Fig. 4 *a*, Sequencing strategy for the coding portion of TT11 cDNA clones. The *EcoRI* sites are generated by the RI linkers. Thin lines indicate 5'-end labelling with polynucleotide kinase and thick lines indicate 3'-end labelling with the large (Klenow) fragment of DNA polymerase I. *b*, The determined nucleotide sequence and the predicted amino acid sequence. The numbers above the amino acid sequence designate the residue positions. The leader, variable, possible D, joining, constant, transmembrane and cytoplasmic regions are indicated although the exact boundaries are somewhat ambiguous. Cysteines are circled. Potential signal sequences for N-linked glycosylation are indicated by CHO.

yet, as it is approximately the same size as immunoglobulin and T-cell receptor β -chain *V* regions, at least some fractions of the species will not have *C* region-hybridizable sequences. One complication in such a screening protocol is the fact that even phenotypically identical cell lines and hybridomas appear to differ by a small but significant fraction of their gene expression (0.2–0.4%; M.M.D., S. M. Hedrick and W. E. Paul, unpublished observation), perhaps through random gene loss or activation. As β -chain mRNA expression is generally much lower than this in hybridomas (0.02%)²⁰, it was necessary to subtract the probe with two separate mRNAs (as shown in Fig. 1) from T cells which do not share the same specificity. C10 and EL-4 have distinct T_H phenotypes similar to 2B4 but are not cytochrome *c*-reactive. There is, of course, some uncertainty in constructing such strategies (see Fig. 1) because even with cells of differing specificity, the same or cross-reactive *V* regions may be expressed. Seven positive plaques obtained in this primary screen were rescreened with another cDNA probe made from the membrane-bound polysomal RNA of 2B4 subtracted with RNA from the macrophage line, P388D₁ (ref. 32). This provides an additional selection for T-cell receptor molecules^{16,25}. Three of the seven plaques were positive with the MBT_H-Mac probe (using the convention of ref. 16) and two of these three cross-hybridized with each other. The one with the largest insert, TT11, was analysed further.

Pattern of expression and rearrangement

Figure 2 shows that, on Northern blot analysis, TT11 is T-cell-specific, as it is not expressed in the B-cell lymphoma (Bal 17), a plasma cell line (M104e), a macrophage line

(P388D₁) or a fibroblast line (3T3). It is expressed in all T cells currently surveyed, including the two, used in the T^H -T subtractions: EL-4 (Fig. 2) and C10 (data not shown), as well as in three T_c -cell lines (T.L. *et al.*, work in progress). It is interesting to note the two distinct bands at 1.8 and 1.3 kilobases (kb) in the EL-4 lane; the possible significance of this with respect to *D*-like regions in this molecule will be discussed below.

The gene(s) encoding the TT11 cDNA clone show distinct signs of rearrangement (Fig. 3), characteristic of all the immunoglobulin-like B-cell-(IgH, Ig κ and Ig λ)³³ and T-cell-(β , HDS4)^{16,25} derived genes. Arrows in Fig. 3 indicate bands which have changed position with respect to the parental genomes in the T-cell DNAs. FN1 and FN13 are keyhole-limpet haemocyanin (KLH)-reactive T_H hybridomas (referred to in ref. 34 as FN1-18 and FN13-21) derived, respectively, from BALB/c $\times$ C57B/6 strain mice and the AKR strain thymoma line, BW5147. In Fig. 3a, a new band appears in a *HindIII* digest of FN1 (arrow) with respect to parental DNAs. In Fig. 3b, one band in an *EcoRV* digest of AKR liver DNA disappears in BW5147, and an *EcoRI* digest shows a new band appearing in BW compared with the parental liver DNA (data not shown). In Fig. 3c, the arrows indicate two bands which are polymorphic for an *XbaI* digest of C57B/6 DNA; both of these bands are present in the FN1 hybrid but only one occurs in FN13, which could only be due to a rearrangement or partial deletion of the chromosome. Figure 3d shows a new band in FN1 versus the parental DNA samples in a *BglII* digest. Although no digest shows evidence of rearrangement in all T-cell DNAs, these results provide sufficient indication of such events to suggest that TT11 is another T-cell receptor-like gene.

Fig. 5 Similarities of the TT11 amino acid sequence to variable (a) and constant (b) regions of a murine T-cell receptor β -chain 86-T1, HDS4 and immunoglobulin. Similarities are boxed, with gaps represented by dashes (-).

TT11 homology with immunoglobulins

The TT11 cDNA clone was partially sequenced by the procedure of Maxam and Gilbert³⁵ using the strategy shown in Fig. 4a; the sequence is shown in Fig. 4b. The clone was oriented by a poly(A) stretch (~150 nucleotides) at the 3' end and sequencing of the 5' half revealed a long open reading frame of 810 nucleotides, with an initiation codon (ATG) within the first 12 nucleotides (Fig. 4b). The sequence has regions similar to the immunoglobulin leader, variable regions, J region and constant region, as is the case also for the T-cell receptor β -chain^{17,18} and the HDS4 gene clone of Saito *et al.* Also, as in the latter two T cell-specific genes, TT11 has an extra cysteine outside the putative intra-domain cysteines in the constant region (which probably bonds to another chain), followed by a transmembrane portion and a potential cytoplasmic region, all of which are encoded as separate exons in the β -chain genes^{36,37}. There are four potential N-linked glycosylation sites, as indicated in Fig. 4b, similar to the four or five found in different β -chain sequences^{17,20}. Probably only three of the four potential sites are available for glycosylation as the most carboxy-terminal one is embedded in the putative transmembrane region (Fig. 4b).

The exact position at which the murine T-cell receptor protein is processed is unknown, but by analogy with all of the immunoglobulins (H, λ , κ), it should occur just before the glutamine at position +1 (see Fig. 4b). This is consistent with the finding that murine α -chains are blocked at their N-terminus (J. Allison, personal communication, and L. Samelson, personal communication). Alternatively, based on the N-terminal amino acid sequence of the human β -chain from the REX T-cell line¹⁹, the processing point would be just before the asparagine at position +3. In the first case, the molecular weight would be 27.8K, in the second slightly less; this agrees well with the data of Allison and colleagues²⁷ who obtained a molecular weight of 27K from a murine α -chain stripped of N-linked sugars with endoglycosidase F.

Comparisons with other putative T-cell receptor molecules and immunoglobulin V, C and J regions are shown in Figs 5 and 6, respectively. While the overall homology of the putative V and C regions with their immunoglobulin counterparts (10–26%) is relatively low, many of the conserved residues found

in all of five known immunoglobulin-like genes are present, particularly in the V region (Fig. 5) and J-region elements (Fig. 6). The cysteines in the TT11 variable region are 65 amino acids apart, which is identical to the spacing in the light chains, and the sequence WYRQ starting at residue 35 and DSA-Y-CAV at residues 83–91 are also highly conserved in most immunoglobulin and T-cell receptor V regions. As with the β -chain and HDS4, the putative J region is the most highly conserved portion, with 7 out of 16 residues homologous with the β -chain consensus sequence³⁶ and 9 out of 16 the same as J_T3 (ref. 36). Whereas the constant region has the least homology of any of these (10–15%), its overall structure is very similar to that of β -chain and HDS4. Somewhat more homology (up to 259) may be obtained in the constant region by using the cysteine at position 204 as the intradomain linkage, but this complicates matters with respect to the presumptive β -chain linkage.

Also characteristic of the T-cell receptor sequences, and shared with TT11, is the sequence ILLK in the putative transmembrane region. The conservation of a charged amino acid (lysine or K) in a transmembrane region is unusual and is not found in other members of the immunoglobulin superfamily; its presence in all three of the putative T-cell receptor molecules may indicate that some unusual multi-chain structure is formed with other molecules in the membrane.

Table 1 Frequencies of T-cell receptor expression

	$C_T\beta$	TT11	HDS4
Thymus	0.2%	0.01%	0.002%
Con A stimulated spleen	0.1%	0.03%	0.002%
2B4	0.02%	0.03%	<0.001%

Approximately 200,000 phage from each library were screened by standard procedures in duplicate. The $C_T\beta$ probe was 86T5 (ref. 17), a DJC²²-containing cDNA clone; the HDS4 probe was a 150-nucleotide synthetic polymer corresponding to the constant region of HDS4 from a.a. 120 → a.a. 180. The former was labelled by nick-translation and the latter by a fill-in reaction with Klenow polymerase. The TT11 probe was labelled by nick-translation.

S	G	N	K	L	I	F	G	T	G	T	L	S	V	K		TT11

Fig. 6 Amino acid homologies among the putative J region of TT11 and the J-region sequences of a murine T-cell receptor β -chain, J_{T3}, HDS4 and immunoglobulins. Similarities are boxed, with variable residues represented by dashes (-).

Possible D regions

Another interesting feature of the TT11 sequence analysis is the strong indication that D regions are present in this molecule just as in the β -chain of the T-cell receptor²⁰⁻²³ and immunoglobulin heavy-chain genes³³. In particular, just 5' to the SGN amino acid sequence of the putative J region (which marks the 5' border of J_{T3} in the β -gene complex), there is the nucleotide sequence GGGGG. This sequence occurs at the point where a D-region element would begin in the β -chain and is characteristic of the β -gene D regions (7 out of 14 contain runs of between 3 and 7 Gs on their 3' side)³⁸ as well as many immunoglobulin heavy-chain D regions³³. Although postulated to be the result of enzymatic addition in immunoglobulins⁴⁸, at least in some β -chain and Igh D regions, these poly(G) sequences are present in germ-line sequences^{22,23}. None of the immunoglobulin light-chain V-region genes sequenced has such poly(G) sequences before the J element junction³⁹. The Northern blot data of Fig. 2, where two bands are clearly visible in EL-4 (and other T_H lines, data not shown), also support the existence of independently assorting D gene segments. This two-band pattern is characteristic of the DJC transcript of the β -chain which is 300 nucleotides shorter than the VDJC transcript^{22,23}. Taken together, these data suggest that the TT11 gene will have D segments, adding to the potential diversity.

Frequency of expression

One characteristic of mRNA species which contributes to a multimeric structure is that they appear to be present in equal or nearly equal percentages in the steady-state mRNA population in cases that are known. Immunoglobulin heavy and light chains⁴⁰, Ia α - and β -subunits⁴¹, H-2 and β_2 -microglobulin⁴², and α - and β -globins⁴³ all follow this rule to within a factor of ≈ 2 . Although differential translation efficiencies or turnover rates could conceivably produce large differences in subunit mRNA frequencies, they do not seem to do so in these cases. To compare the steady-state mRNA frequencies in a relatively quantitative manner, we surveyed thymocyte, concanavalin A (Con A)-stimulated spleen and 2B4 cDNA libraries with TT11, HDS4 and C_T β probes. The results (Table 1) indicate that TT11 and C_T β are present in fairly similar frequencies (1:1-1:3) in the 2B4 and Con A spleen libraries, whereas HDS4 is much rarer, being present in $\frac{1}{50}$ th the amount of β -chain in the Con A spleen library and absent from the 2B4 library. This equivalence in frequency, together with the other data presented here, makes TT11 a more attractive candidate for the α -chain of the receptor in most T cells. Also of interest from the data in Table 1 is the change in the ratio of TT11 to β -chain in immature versus mature T cells. Specifically, the TT11/ β -chain ratio changes from 1:20 in thymocytes to 1:3 in Con A-stimulated spleen cells, suggesting that TT11 gene expression (and perhaps rearrangement) may occur after that of the β -chain, analogous to light-chain immunoglobulin expression following that of the heavy chain in B cells³³.

How many T-cell receptor gene families?

Regardless of whether TT11 or HDS4, or neither, encodes the T-cell receptor α -chain, there is already an overabundance by

at least one of immunoglobulin-like T cell-specific genes which rearrange in some types of T-cells. The reason for this cannot be explained based on the present biochemical evidence, and may involve variations of a two-receptor model of T-cell recognition⁴⁹. Although the strict 'two-receptor' model for MHC-antigen co-recognition has been excluded by several convincing experiments^{44,50}, there exists the possibility that in at least some circumstances an alternative heterodimer might be able to form for some purpose related to this event.

We thank Dr J. Casey for the gift of random primer DNA, Dr C. Benoist for the thymocyte and spleen cDNA libraries, Dr C. Bona and colleagues for the FSN-1 and FSN-13 DNAs, Dr E. Ruley for 3T3 mRNA, Dr K. Arai and colleagues for the HDS4 probe, Dr J. Rothbard for the molecular weight calculation and G. Samuel and K. Redman for secretarial assistance. D.M.B. was supported in part by a fellowship from the Lupus Foundation, T.L. is a fellow of the Damon Runyon-Walter Winchell Cancer Fund and D.C. was a fellow of the Leukemia Society of America. This work was supported by grants to M.M.D. from NIH and the American Cancer Society.

Note added in proof: Amino acid sequencing of a human T-cell receptor α -chain (N. Jones and J. L. Strominger, personal communication) suggests that TT11 is the murine homologue. Also, most of the 8-10 bands seen on Southern blot (Fig. 3) with a TT11 probe hybridize to the variable portion of the molecule. This contrasts with results obtained with V _{β} probes²⁴ and suggests that V _{α} may be immunoglobulin-like.

A third rearranged and expressed gene in a clone of cytotoxic T lymphocytes

Haruo Saito, David M. Kranz, Yohtaroh Takagaki, Adrian C. Hayday, Herman N. Eisen & Susumu Tonegawa

Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

In addition to the two previously identified genes rearranged and expressed in a cytotoxic T-lymphocyte clone, we have identified a third gene that is also rearranged and expressed in the same clone. This new gene shows clonal diversity, codes for a polypeptide chain that contains immunoglobulin-like variable and constant domains, carries potential N-glycosylation sites and is a particularly attractive candidate for the gene that encodes the α -subunit of the heterodimeric antigen receptor of this T-cell clone.

IN spite of its central roles in both regulatory and effector phases of the vertebrate cellular immune system, the chemical nature of the T-cell antigen receptor has been elusive¹. A particularly intriguing question about this receptor concerns the molecular basis for its dual recognition of antigens in conjunction with self major histocompatibility complex (MHC) products²⁻⁴. Unlike immunoglobulins, which recognize and bind free antigens, the T-cell antigen receptors characteristically recognize cell-bound antigens in the specific molecular context of self-MHC molecules. Recently, several groups have succeeded in making antisera and monoclonal antibodies that are specific for individual T-cell clones⁵⁻⁷ and which presumably recognize clone-specific determinants on the T-cell antigen receptors. The receptor thus characterized is a heterodimeric glycoprotein of apparent relative molecular mass (M_r) ~90,000, consisting of an α -subunit (M_r 42,000–44,000) and a β -subunit (M_r 42,000–44,000) held together by an inter-chain disulphide bond(s). Peptide fingerprint analyses of α - and β -chains from several T-cell lines suggest that both subunits are composed of variable (V) and constant (C) regions⁸⁻¹⁰.

During the past year, three groups have isolated cDNA clones [YT35 (ref. 11), TM86 (ref. 12), pHDS11 (ref. 13) and pHDS4/203 (ref. 13)] that probably correspond to T-cell receptor genes. As YT35, TM86 and pHDS11 from a human T-cell tumour, a mouse T helper hybridoma and a mouse cytotoxic T lymphocyte (CTL) clone, respectively, are all extensively homologous to each other at the 3' half, it was concluded that they correspond to the same gene. Recently, partial amino acid sequences determined by direct analysis of the β -chain of a human T-cell receptor showed that YT35, TM86 and pHDS11 represent the gene for this subunit¹⁴. Although there is no extensive nucleotide homology between the fourth clone, pHDS4/203, and the other three cDNA clones, all share several common properties. (1) They are expressed in T cells but not in B cells. (2) The corresponding genes are rearranged in T cells and not in B cells. (3) In the encoded proteins there are distinctive regions that, proceeding from amino- to carboxy-terminus, correspond to a signal peptide, two immunoglobulin-like domains, a transmembrane peptide rich in hydrophobic amino acids and a short cytoplasmic peptide. (4) Their deduced amino acid sequences have low but significant homology to those of immunoglobulin chains. (5) Each gene is composed of separate V, J and C gene segments¹⁵⁻¹⁸ (in the cases of YT35 and TM86, the corresponding genes have also been shown to have D segments^{19,20}). (6) Their V, (D) and J segments have characteristic signal sequences for gene rearrangement (heptamer and nonamer separated by either 12 or 23 base pairs (bp); refs 15, 16, 18–20 and A. Hayday *et al.*, unpublished data).

The cDNA clone pHDS4/203 therefore satisfied many of the

properties expected for the α -chain of the T-cell antigen receptor. However, this clone lacks sequences that correspond to sites for N-linked glycosylation and it has recently been shown that both the α -chain and the β -chain of another type of T cell, helper cells, are N-glycosylated (J. P. Allison, personal communication). Although it was possible that the α -chain of the CTL clone from which pHDS4/203 was isolated is not N-glycosylated, it also seemed possible that there is still another gene (or genes) whose properties are similarly consistent with those expected for the α -subunit of the T-cell receptor. Accord-

Table 1 T cell-specific clones from a subtracted CTL cDNA library

Group	Size of mRNA (kb)	No. of clones	Rearrangement	Representative clone
T (thy1)	2.0	19	No	pHDS1
B	0.8	19	No	
C(β)	1.4	18	Yes	pHDS11
F	1.7	13	No

Two hybridization probes were used to screen the cDNA library. The first was the 2C cDNA prepared from the poly(A)⁺ RNA of membrane-bound polysomes by subtraction with poly(A)⁺ RNA from a B-cell lymphoma, CH-1. The second was the cDNA prepared from the total poly(A)⁺ RNA from another B-cell lymphoma A20-2J. After screening about 20,000 independent transformants, we have identified a total of 140 putative T cell-specific cDNA clones and grouped these clones on the basis of the corresponding genes, using the following procedures. First, plasmid DNA preparations from each of 20 randomly chosen cDNA clones were used as hybridization probes in RNA blotting analysis of 2C poly(A)⁺ RNA and DNA blotting analysis of 2C and embryo DNA. The hybridization patterns allowed assignment of these clones to 12 groups. Second, mouse DNA inserts were dissected from a representative cDNA clone of each group and used as probes for colony hybridization of all of the cDNA clones; the results allowed assignment of 105 clones among the 12 groups. The above procedures were repeated for some of the remaining unassigned clones.

Fig. 1 Southern blot analyses²² of DNA from BALB/c embryo, myelomas MOPC315 and MOPC460 (both BALB/c-derived) and CTL lines 2C, G4, 1.5.2 and 2.1.1 (all BALB.B-derived²¹). DNA was digested with the indicated restriction enzymes, electrophoresed through 0.8% agarose gels, blotted onto nitrocellulose and hybridized with the ³²P-labelled, nick-translated insert from clone pHDS58. Hybridization was carried out at 42 °C in 50% formamide and 5 × SSC. The filters were washed at 65 °C in 0.2 × SSC. Separate experiments showed that BALB/c and BALB.B embryo patterns are indistinguishable. Numbers on the left-hand side are *M_r* markers.

ingly, we have analysed further the cDNA library from CTL clone 2C and report here the isolation of a third class of cDNA clone representing a gene whose protein product is a better candidate for the α -subunit of the T-cell $\alpha\beta$ heterodimer receptor than is pHDS4/203: the new gene is rearranged and expressed specifically in T cells, its product has the sequences expected of an integral membrane protein and it carries potential N-glycosylation sites.

Classification of cDNA clones

We reported previously¹³ construction of a 'subtracted' cDNA library from an alloreactive CTL clone (2C) specific for the product of a gene at the *D* end of the *H-2* complex²¹. We subjected this library to differential screening using two hybridization probes (Table 1). From these experiments, it was established that 120 of 140 putative T cell-specific cDNA clones originally identified, belonging to 16 different groups, are expressed specifically in CTL clone 2C and not in B cells. Table 1 lists the number of cDNA clones in each group and the size of poly(A)⁺ RNA they detected by Northern hybridization. Of the remaining 20 cDNA clones, 12 belonged to two gene groups whose expression in B cells was substantially lower than in T cells but still definitely detectable. The other eight cDNA clones contained relatively short inserts (less than 250 bp) and have not yet been characterized.

Among the 16 T cell-specific cDNA groups, we identified four whose genes seemed to be rearranged in CTL clones. Two (pHDS11 and pHDS4/203) of the four have been described previously¹³. The characteristics of the third group, represented by pHDS58, are the main subject of the present report. The fourth cDNA, represented by one member, pHDS86, hybridized to an extra DNA fragment when *Pvu*II digests of clone 2C DNA and embryo DNA were compared; however, nine other restric-

Fig. 2 RNA blot analyses²³ of poly(A)⁺ RNA from various B- and T-cell lines. Probes: *a*, total insert of pHDS58; *b*, *Hpa*II fragment containing 270 bp at the end of the pHDS58 insert (V-region probe). RNA was extracted from B-cell lymphomas A20-2J and CH1 and alloreactive (H-2^b anti-H-2^d) cytotoxic T-lymphocyte clones 2.1.1, 1.5.2, G4 and 2C. Approximately 1.5 μ g of poly(A)⁺ RNA was denatured with glyoxal and electrophoresed through a 1% agarose gel in 10 mM sodium phosphate buffer (pH 6.5). RNA was transferred to a nitrocellulose membrane and hybridized to ³²P-labelled nick-translated probe DNAs. The conditions of hybridization and washing are given in Fig. 1 legend. The filter used for hybridization with the first probe was washed by boiling at 100 °C for 5 min in H₂O and re-used for hybridization with the second probe.

tion enzymes failed to show any evidence of rearrangement (data not shown).

Gene rearrangement in T cells

Figure 1 shows the results of Southern blot analyses²² of DNA from BALB/c embryos, four CTL clones of different specificities and two myelomas that have been digested with *Eco*RI, *Kpn*I or *Bgl*II and hybridized with the insert of pHDS58. With each of the three enzymes, clone 2C DNA showed an extra fragment that was not detected in the digest of embryo DNA. DNA from the other CTL clones gave hybridization patterns which lacked several fragments detected in embryo DNA. In contrast, the hybridization patterns of DNA from the myelomas and embryos were indistinguishable. These results strongly suggest that the gene or genes corresponding to clone pHDS58 are rearranged in cytotoxic T cells but not in myelomas.

The expression of the pHDS58 genes in CTL clones and B lymphomas was examined by Northern hybridization analyses²³ of poly(A)⁺ RNA. When the whole insert of pHDS58 was used as the hybridization probe, no hybridization was detected in the two B-cell lymphomas, but poly(A)⁺ RNAs of distinct sizes were detected in all four CTL clones (Fig. 2*a*). The size of the major RNA species in 2C (1.7 kilobases, kb) was slightly greater than that in the other three CTL clones (1.6 kb). In addition, minor RNA species of about 1.2 kb were detected in all four CTL clones. When a DNA fragment containing 270 bp from the 5' end of the pHDS58 insert was used as the hybridization probe, only the 1.7-kb RNA species of 2C was detected and the other three CTL clones and the B-cell lymphomas exhibited no hybridization (Fig. 2*b*; see Fig. 3 for the region of the cDNA sequence covered by the probe). These results suggest that the 1.6–1.7-kb RNA is composed of a common 3' sequence (C region) and a CTL clone-specific 5' sequence (V region), as has been seen with immunoglobulin and the T-cell receptor β -chain.

Fig. 3 Restriction map of the insert of cDNA clone pHDS58. The map was constructed by a combination of single and double restriction enzyme digestions of the plasmid DNA. The V, J, C and 5'- or 3'-untranslated regions are shown by shading, black, hatching and white, respectively. Also shown is the sequencing strategy used to determine the nucleotide sequence shown in Fig. 4. The arrows indicate the directions and the extent of sequence determination. The open and closed circles indicate that the ends of the DNA fragments labelled are 5' and 3', respectively.

Fig. 4 The nucleotide and predicted amino acid sequences of the cDNA clone pHDS58. The nucleotide sequence was determined by the method of Maxam and Gilbert²⁴ according to the strategy shown in Fig. 3. Numbers given above the amino acid sequence designate amino acid residue positions. The numbers on the right show nucleotide positions. The V, J, C, TM (transmembrane) and CY (cytoplasmic) regions are indicated by horizontal arrows although exact boundaries are ambiguous. Cysteine residues thought to be involved in intradomain or inter-chain disulphide linkages are encircled. The potential N-glycosylation sites (N-X-S or N-X-T) are also indicated.

Nucleotide sequence

The restriction map and the sequencing strategy of the pHDS58 insert are shown in Fig. 3. The entire nucleotide sequence of 1,372 bp determined by the method of Maxam and Gilbert²⁴ is shown in Fig. 4. The longest open reading frame begins with the Met codon at nucleotide positions 56–58, extends over a stretch of 804 bp, and ends at nucleotide position 859. The amino

acid sequence corresponding to this reading frame is also shown in Fig. 4. For reasons given below, the numbering of codons or amino acid residues starts with the triplet CAG (Gln) at nucleotide positions 116–118. The amino acid sequence immediately following the Met and extending to the Gln is highly hydrophobic and reminiscent of a signal peptide²⁵. After the Gln, the sequence is significantly homologous to those of the T-cell

Fig. 5 Comparisons of the V and C regions of the predicted amino acid sequence of pHDS58 and the V and C regions, respectively, of the predicted or determined amino acid sequences of five other polypeptide chains: a chain encoded by pHDS4/203, the β -chain encoded by pHDS11 (ref. 13), 93G7 γ 1 immunoglobulin heavy chain, MOPC603 κ light chain, and MOPC104E λ 1 light chain²⁶. Those residues common between the pHDS58 protein and any one of the other five chains are boxed. *. The residues common among all six chains. Approximate boundaries of framework and hypervariable regions as they appear in immunoglobulin V regions are indicated by horizontal arrows. The amino acid positions refer to those of pHDS58 protein.

receptor β -chain deduced from pHDS11 and the polypeptide chain encoded by pHDS4/203, as well as to the sequences of an immunoglobulin heavy chain (93G7), an immunoglobulin κ light chain (MOPC603) and an immunoglobulin λ 1 light chain (MOPC104E)²⁶.

The homology is shown in Figs 5 and 6, where the pHDS58 amino acid sequence is compared with the V (or V + D), J and C region sequences of the other five polypeptide chains. Sequence homology is evident in all three regions, but is most striking in the J region, where it amounts to 38–62%. In the V regions, the pHDS58 sequence is related to the other five sequences by 22–29% homology. The six amino acid residues that are conserved in this region among pHDS11, pHDS4/203 and the three types of immunoglobulin chains (Gln, Cys, Trp, Gln, Tyr and Cys at positions 5, 22, 34, 37, 88 and 90, respectively) are also shared by pHDS58. The sequence homology is least in the C regions, where it ranges over 12–20%. Nevertheless, the relatedness is evident around the two Cys residues that form intradomain disulphide bonds in immunoglobulin chains. Throughout the V, J and C regions, the pHDS58 sequence, like the pHDS11 and pHDS4/203 sequences, is more homologous to the light chains (25% and 27% for κ and λ , respectively) than to the heavy chain (23%).

Beyond the C region, the pHDS58 polypeptide chain exhibits no obvious sequence homology to the corresponding regions of the β -chain (pHDS11) or the chain encoded by pHDS4/203. Nevertheless, the three polypeptide chains are organized in a very similar fashion in these regions. Thus, as in the pHDS11 and pHDS4/203 chains, the C region of the pHDS58 chain is followed by a peptide carrying an extra cysteine, then by a stretch of about 20 hydrophobic residues that could correspond to a transmembrane peptide and finally by a short hydrophilic C-terminal peptide that presumably extrudes into the intracytoplasmic space.

In Fig. 4 these regions of pHDS58 are indicated by horizontal arrows. The exact boundaries of a few adjacent regions are somewhat uncertain. For instance, it is not possible to determine unambiguously the N-terminus of the processed protein from the nucleotide sequence of the cDNA alone. However, the Gln at nucleotide positions 116–118 is the best candidate for the following reasons. First, the proposed assignment places the first Cys residue at position 22, while the corresponding Cys

residues of most immunoglobulin chains are at position 22 or 23 (ref. 26). Second, most immunoglobulin chains carry a signal peptide 19–22 residues long²⁶; the present assignment makes the proposed signal peptide 20 residues long. Finally, the pHDS58 chain is an excellent candidate for the α -subunit of the T-cell receptor, whose N-terminal residue has recently been shown to be blocked (S. Schlossman, personal communication), probably by a cyclized glutamine residue.

The proposed processed polypeptide chain is 248 amino acids long and its calculated relative molecular mass is ~28,000. The chain contains 23 negatively charged (15 Asp and 8 Glu) and 19 positively charged residues (6 Arg and 13 Lys), corresponding to an isoelectric point near neutrality in the absence of post-translation modifications. As shown in Fig. 4, it has four potential sites for N-glycosylation.

Conclusions

The pHDS58 gene and its product share several characteristics with the two previously identified T-cell genes, pHDS11 and pHDS4/203, and their products. (1) The gene is specifically expressed in various CTL clones but not in B lymphomas. (2) The gene is rearranged in CTL clones but not in myelomas and the rearrangement pattern varies with the CTL clone. (3) The rearranging poly(A)⁺ RNA is composed of 5'-variable and 3'-constant regions. (4) The primary sequence suggests that the encoded protein is composed of a signal peptide, two immunoglobulin-like domains, each with one disulphide loop,

Fig. 6 Comparison of the J region amino acid sequences of pHDS58 and pHDS4/203 (ref. 13) and consensus sequences of the T-cell antigen receptor β -chain¹⁶ and immunoglobulin J_H , J_κ and J_λ (ref. 26). Those residues common between pHDS58 and any one of the other five J segments are boxed and shaded.

a transmembrane peptide and a cytoplasmic peptide. (5) The two domains are homologous to the V and C domains of immunoglobulin chains, particularly those of λ light chains. (6) Besides having two cysteine residues in each domain, the encoded protein has a fifth cysteine residue in the region between the C domain and the transmembrane peptide, that is, at a position where the chain might be disulphide bonded to another chain¹³.

The counterparts of the pHDS11 gene in a mouse T-helper hybridoma and a human T-cell tumour have been identified previously by Hedrick *et al.*¹² and Yanagi *et al.*¹¹ and shown to code for the β -subunit of the heterodimeric T-cell receptor¹⁴. As the nucleotide sequences of pHDS11 and the gene identified by Hedrick *et al.*¹² are virtually identical in the C region, we concluded that pHDS11 codes for the β -subunit of the CTL receptor¹³.

Because pHDS4/203, the second type of rearranged gene discovered in the CTL clone 2C, had many characteristics expected for a T-cell receptor gene, it was originally thought to code for the other (α) subunit of the CTL receptor¹³. Subsequently, endoglycosidase F digestion of the $\alpha\beta$ heterodimers of mouse helper T cells and a human T-cell tumour suggested that both subunits of these T-cell receptors are N-glycosylated (J. P. Allison, personal communication; C. A. Janeway, personal communication), but the pHDS4/203 gene, unlike the pHDS11 gene, has no typical N-glycosylation sites (namely, the tripeptide

Asn-X-Ser/Thr)¹⁵. Although the difference in the source of T cells (that is, CTL versus helper and mouse versus human) could have explained the apparent discrepancy, our recent studies suggest that the α -subunit of CTL clone 2C is also N-glycosylated (unpublished data). It is therefore of particular interest that the newly discovered pHDS58 gene reported here not only possesses all of the properties expected for a T-cell receptor gene but also carries four potential N-glycosylation sites. Thus, while there is no direct evidence, the pHDS58 gene must be considered a better candidate than pHDS4/203 for the α -subunit.

If the pHDS58 gene encodes the α -subunit and pHDS11 the β -subunit of 2C clone $\alpha\beta$ heterodimeric receptor, what is the function of the pHDS4/203 gene? As this gene exhibits clonal diversity, in common with the other two genes, it also is likely to be involved directly in determining T-cell specificity. If so, this raises the possibility of a second receptor. The idea of a second receptor has been previously discussed at length²⁷⁻³² but is at present less favoured than the one-receptor hypothesis³³⁻³⁶. The role of the third gene should be clarified by analysis of its product, currently underway.

Structure, expression and divergence of T-cell receptor β -chain variable regions

Phillip Patten*, Takashi Yokota[†], Jonathan Rothbard[‡], Yueh-hsiu Chien[‡], Ken-ichi Arai[†] & Mark M. Davis[‡]

[†] Department of Medical Microbiology and ^{*} Department of Biological Sciences, Stanford University School of Medicine, Stanford, California 94305, USA

[‡] DNAX Research Institute for Molecular and Cellular Biology, Palo Alto, California 94306, USA

Analysis of three new T-cell receptor β -chain variable regions together with those in the literature indicates that they have both remarkable similarities and differences with those of immunoglobulin. Less than 10 V regions appear to predominate in the thymus. V β sequences are much more heterogeneous at the amino acid level than are immunoglobulin V regions and they appear to diverge between species much more quickly, apparently the result of additional hypervariable regions. Three of these putative new hypervariable regions lie outside of the classical immunoglobulin binding site, an indication that important interactions may be occurring in these regions with polymorphic MHC determinants.

RECOGNITION of foreign entities by T cells appears to involve molecules and mechanisms strikingly similar to those involving immunoglobulins. Analysis of T-cell receptor β -chain cDNA clones and the genes encoding them has revealed V, D, J and

C regions similar in size and sequence to the corresponding immunoglobulin elements¹⁻¹⁰. The V, D and J genomic elements are rearranged during T-cell differentiation to form a single exon, as is the case for immunoglobulins and this rearrangement

appears to be mediated by flanking sequences analogous to those of immunoglobulins⁴⁻⁸. However, these studies have not revealed how the T-cell receptor polypeptides differ significantly from immunoglobulins to account for the recognition phenomena unique to T cells. Specifically, the structural bases of the requirement for simultaneous recognition of both antigen and self-major histocompatibility complex (MHC) determinants and the antigen-independent process of 'learning' self-MHC, which presumably occurs in the thymus^{11,12}, remain obscure. To address these questions, we studied the V-region sequences of β -chains isolated from various T-cell lines and hybridomas. We have begun to define the putative binding site(s) of this molecule by identifying framework (conserved) and hypervariable (nonconserved) regions, according to the precedent of Wu and Kabat¹³ in immunoglobulins. We also demonstrate that β -chain variable regions appear to diverge between species much more rapidly than immunoglobulin variable regions, consistent with a larger fraction of the molecules encoded by the former being devoted to interaction with variable determinants (MHC and antigen). In addition, we have used these V regions to assess the overall repertoire of T-cell specificities in the thymus through the frequency with which these V regions are used in thymic T-cell populations.

β -Chain cDNA clones from helper T-cell lines

T-cell lines generated by growing fetal liver and/or bone marrow cell suspensions in conditioned media have proved to be an important source of cloned, non-transformed cells of defined specificity. cDNA libraries from four such cell lines¹⁴⁻¹⁶ were

constructed (as described by Okayama and Berg¹⁷) from poly(A)⁺ RNA made from concanavalin A (Con A)-stimulated cells, using the pcD vector¹⁸. Three of the cell lines have a T-helper (T_h) phenotype in that they respond to antigen and class II MHC determinants by secreting growth factors¹⁵⁻¹⁶. These lines are E1, which is reactive to trinitrophenol (TNP) on a BALB/c MHC background (I-A^d-restricted)¹⁵; C5, which responds to the dinitrophenol (DNP)-ovalbumin conjugate on a BL/6 background (I-A^b-restricted)¹⁵; and LB2, which recognizes chicken red blood cells, also on a BL/6 background (I region-restricted)¹⁶. About 0.1-0.4% of the cDNA clones are positive for the β -chain T-cell receptor gene, a frequency similar to that of a total thymocyte cDNA library and considerably higher than that of T-helper cell hybridomas (0.01-0.02%)^{4,19}. This higher level of transcription of the β -chain in T helper lines is consistent with reports that cell lines, in contrast to hybridomas, have been shown to bind antigen and hence may have more T-cell receptor protein on their cell surface than hybridomas²⁰. A fourth cDNA library was constructed from the RNA of a suppressor T-cell line, Ly 23/4 (ref. 14) and had a similarly high level of β -chain-positive cDNA clones. Of 25 such cDNA clones surveyed, none appeared to have V regions. Instead, all 25 clones were in a size range expected for transcripts from D-J joining events^{7,9} and sequence data from one of these clones confirmed this interpretation (data not shown). This is in contrast to the half to two-thirds of the β -positive cDNA clones from the other libraries which have V regions, and may be related to the apparent absence of β -chain expression in murine T-suppressor hybridomas²¹.

Fig. 2 Amino acid homologies between the seven β -chain variable-region sequences available. Homologies between four or more sequences are boxed. Both V- and D-region sequences are shown. Potential N-linked glycosylation sites are circled.

cDNA clones with complete V_β coding regions were isolated from the E1, C5 and LB2 libraries and their nucleotide sequences were determined by the method of Maxam and Gilbert²² according to the strategy in Fig. 1. All of these transcripts derive from the 3' most $J-C$ locus ($J_7\beta'-C_7\beta'$)⁶, as do the sequences of all four of the other full-length cDNAs derived from functional lines, hybrids or lymphomas^{4,23,24}. Although cDNA clones in the spleen or thymus appear to rearrange equally well to either of the two loci, at least in the context of a specific V region²⁴, few functional T-cell lines appear to use the 5' most locus (G. K. Sim, personal communication, N. R. J. Gascoigne and J. Elliot, personal communication). As the two C regions are almost identical⁶, the strong bias of such cells for the 3' most locus may reflect a selection for J regions from that cluster and may be an important clue in determining the functional significance of a tandem $J-C$ arrangement of the B -chain locus.

The data presented in Fig. 1 also show that E1 and C5, though reactive with structurally related antigens, share very little sequence homology. This lack of homology may reflect the effect of carrier, as C5 is conjugate-specific for DNP-ovalbumin whereas E1 is hapten-specific for TNP. Alternatively, it could reflect the effect of different restricting alleles (E1, I-A^d; C5, I-A^b) on antigen binding. Another explanation is that the other chain of the receptor (α) binds antigen in these clones. In addition to the lack of homology between the β -chain variable regions of E1 and C5, there is no homology in any portion of these with the antigen-binding portions of known TNP- or DNP-binding immunoglobulins²⁵—a further indication of the very different requirements of T-cell and B-cell recognition and an indication of why receptor isolation schemes involving T- and B-cell lines of matched antigen specificity were unsuccessful²⁶⁻²⁸.

β -Chain V regions in thymus

To assess the relative contributions of various β -chain V regions to the T-cell receptor repertoire, V region-specific fragments were prepared from each of the three cDNA clones described

above; from 2B4.71, a cytochrome c -specific T_H hybrid⁴; and from 86T1 (ref. 2), isolated from a thymocyte cDNA library (see legend to Table 1). These five distinct V-region fragments were labelled and used to screen 250,000 λ gt10 (ref. 29) cDNA clones from a BALB/c strain thymocyte poly(A)⁺ RNA-derived cDNA library (200,000 independent clones). Table 1 shows the percentage of clones in this library that were positive for both the β -chain constant region and these V regions. This analysis indicates that four of the five V regions fall into a uniformly frequent class of transcripts, each representing 1–3% of the C-region hybridizing clones. Since four of these five genes hybridize to single bands, and the fifth to only two bands in genomic Southern blots (see below), these frequencies must largely reflect the expression levels of the loci from which they were derived. The actual frequency of these V_β sequences is even greater since, of 35 C_β-positive clones analysed from this library, only six extended sufficiently far 5' to have hybridizable V regions (data not shown), presumably due to frequent D–J joining events^{7,9} and a 3'-end bias in cloning. The corrected frequencies are indicated in Table 1. Therefore, these four V regions together comprise 8.3% of the total β -chain message, and an even larger fraction (~40%) of functional transcripts. Thus, a relatively small number of V regions, perhaps less than ten, predominate in the thymus. The notion of a small V_β repertoire is supported by the fact that among the six murine V_β s reported here, two have been isolated independently from other functional T cells (86T1²⁴ and LB2, S. Hedrick, personal communication).

In contrast, the 2B4 V region was not detected among 250,000 clones surveyed, and thus must be expressed at a frequency at least 20 times lower. This is consistent with the observation that cytochrome c is a relatively weak antigen and reactive cells are only observed in secondary responses (R. Schwartz, personal communication). There are many such weakly reactive antigens^{30,31} and they may represent a second group of infrequently occurring V regions of unknown repertoire size. The regulatory mechanisms generating such uniformity in the frequency of the abundant class as opposed to the 2B4.71 V region are unknown. This selective expression contrasts with the much more diverse expression of immunoglobulin V regions in B cells, although a single heavy-chain variable region (V_H) seems to be expressed very frequently in early B cells (F. Alt, personal communication).

Additional hypervariable regions

With the sequences presented here, there are now seven β -chain V regions available^{2-4,23} for comparison with respect to framework and hypervariable regions. Homologies between the seven sequences are shown in Fig. 2 and the relevant numerical

Table 1 Variable region usage in a BALB/c thymocyte cDNA library

Variable region	Frequency (%)	Corrected frequency
C5	3.2	9.3%
E1	2.2	12.8%
LB2	0.9	5.2%
86T1	2.0	11.6%
2B4.71	<0.05	—
Total	8.3	38.9%

The following V region and C_β-specific fragments were purified on polyacrylamide gels and nick-translated by standard procedures⁴⁷: 86T1, *EcoRI*–*Bam*HI; 2B4.71, *EcoRI*–*Rsa*I; C5, *Pst*I–*Pvu*II; E1, *Pst*I–*Pst*I; LB2, *Bst*EII–*Xho*I; C_β 86T5², *EcoRI*–*Eco*RI. There were 1,650 C_β-positive clones. The percentage of these that were positive for a given V region is indicated. The corrected frequency is the raw percentage divided by the fraction of C_β-positive cDNA clones bearing V regions. The corrected value for C5 was divided by two as it hybridizes to two bands in genomic Southern blots and hence may cross-hybridize with another expressed V region.

Fig. 3 Hypervariable and framework regions. **A**, Variability plot of the T-cell receptor β -chain V-region sequences shown in Fig. 2, using the convention of Wu and Kabat¹³. The positions of the three hypervariable peaks of immunoglobulin light chains²⁵ are indicated by arrows. Regions of hypervariability are marked by open bars. **B**, **D** and **G** correspond to the classical immunoglobulin hypervariable regions²⁵. Part **B** indicates the homologies between a variety of V_H , V_κ and the seven V_β sequences. Homologies of four or better are indicated by a closed circle, less than four homologies by a dash, and spaces denote gaps inserted to maximize homology. Framework regions of the immunoglobulin sequences are indicated with solid bars. **A**, **C**, **E** and **F** are regions of V_β sequence that correspond to conserved V_κ framework residues, but are significantly more variable in V_β . With the exception of the V_H region of *Caiman crocodylus*³³, sequences are from ref. 25. Immunoglobulin heavy chain (V_H): a, mouse group I MOPC 141CL; b, mouse group II MOPC 104E; c, mouse group III TEPC 601; d, dog MOO; e, rabbit K25; f, human VH26; g, caiman pC3. Immunoglobulin κ -chain (V_κ): a, mouse 10K26-12A1; b, mouse S107B CL; c, dog GOM; d, human group I ROY; e, human group III, 1T1; f, rabbit K9 335; g, rabbit K25. V_T : a, 86T1; b, 2B4.71; c, YT35; d, HDS11; e, E1; f, LB2; g, C5.

comparisons in Table 2. Whereas the least related immunoglobulin V regions are 45% homologous in amino acid sequence and range up to 98% (ref. 25), the most similar V_β regions shown here are 51% homologous and range as low as 18% (Table 2). Although it has been suggested²³ that some of this variability is due to helper and cytotoxic T cells using different sets of V regions, this comparison shows that equally low homologies are observed between T_H -derived V_β 's, and that the cytotoxic T cell-derived V_β HDS11 has 51% amino acid homology with the T_H -derived V_β C5—the highest homology observed between any two V_β s in Table 2. Furthermore, the helper-derived V_β LB2 is nearly identical to nucleotide sequence (one change in 110 nucleotides examined) to a V_β derived from a functional cytotoxic T cell (S. Hedrick, personal communication).

These relatively low levels of homology among β -chain V regions are further analysed in the Wu-Kabat variability plot in Fig. 3A; this follows the formula (no. of different amino acids)/(frequency of the most common amino acid)¹³ and serves to highlight regions of maximum variability. Both heavy- and light-chain immunoglobulins exhibit three hypervariable peaks when plotted in this manner, two in the main body of the V region (CDR1 and CDR2) and a third corresponding to the V-J joint in light chains and the V-D-J joint in heavy chains²⁵ (indicated by arrows in Fig. 3A). In contrast, the V_β sequences examined in Fig. 3 exhibit seven distinct variability peaks, three of which correspond almost exactly to the canonical immunoglobulin κ light-chain hypervariable regions. Two of the peaks (A and F) correspond to regions in V_H and V_κ that have been shown to be significantly more variable than classical framework regions^{25,32} but less variable than the classical hypervariable regions. The third and fifth peaks (C, E), however, do not have any precedent in immunoglobulins.

Complementary to these variability data are the homology comparisons shown in Fig. 3B; in this representation, four or more identical residues out of seven are displayed as solid circles

and fewer than four as dashes. In a control for the validity of conclusions based on a small number of sequences, a similar comparison is made of seven V_κ and V_H sequences^{25,33}, chosen for maximum variability. In this analysis, the classical hypervariable (HV) and framework (FR) regions of immunoglobulins (indicated by solid bars under immunoglobulin sequences) are picked up remarkably well. By comparison, the β -chain V regions have stretches of homology flanking the conserved tryptophan and cysteines that are comparable with those in immunoglobulin FR regions. However, there are four new regions of sequence, corresponding to the four new peaks of variability in Fig. 3A, whose V_κ equivalents are conserved FR residues, but which are much more variable in V_β (Fig. 3B, regions A, C, E, F). As discussed below, the sequence variability in these regions may have important consequences for antigen-MHC interactions.

Rapid divergence of β -chain V regions

There are two interpretations that are consistent with the remarkably low levels of homology between the V_β s reported here relative to immunoglobulin V regions. Cellular immunity could significantly predate humoral immunity and V_β s could evolve at a rate comparable to immunoglobulin V regions; the difference in homology between V_β s being then a result of having diverged from each other much earlier than immunoglobulin V regions. Alternatively, there could be significantly different selective pressures on V_β s as a consequence of the requirements of Ag-MHC interactions unique to the T-cell receptor. In the case of immunoglobulin, those portions of the V_H regions that interact with antigen (HV regions) acquire mutations at a much greater rate than do framework regions. Specifically, HV regions appear to diverge at the rate of unselected DNA, whereas FR regions evolve at a rate comparable to globin genes³⁴. These HV regions make up 22% of both V_H and V_κ ²⁵, whereas the analysis in Fig. 3 shows that ~54% of V_β may be hypervariable. If these putative new HV regions evolve at a rate comparable to those

Fig. 4 Interspecies homologies of β -chain variable regions. *Eco*RI digests of mouse (BALB/c), rat, hamster (CHO), ground squirrel, rabbit and human DNAs were electrophoresed through 0.9% agarose and blotted onto nitrocellulose by standard procedures⁴⁷. V-region specific fragments from five of the β -chain clones and one from an immunoglobulin heavy chain (S107 V), were nick-translated and hybridized overnight at 55 °C in $6 \times$ SSC and washed at the same temperature, the final wash using $0.2 \times$ SSC for 30 min. Size markers are indicated in kilobases. Divergence time from mice (millions of years)^{36,37}: rat, 15 Myr; hamster, 25 Myr; ground squirrel, 60 Myr; rabbit, 70 Myr; human, 90 Myr.

of immunoglobulin, the V_{β} gene as a whole should evolve much more rapidly than V_H or V_{κ} genes.

To resolve between these interpretations, we used nucleic acid hybridization as an assay for the divergence of five murine V_{β} s and a representative V_H (S107)³⁵ from their homologues in other species. We reasoned that if a much larger fraction of V_{β} s is indeed hypervariable, hybridization of V region-specific probes with their homologues in successively more distantly related species should fall off much more rapidly for V_{β} than for V_H . Figure 4 shows a survey of six mammalian genomes, spanning 90-Myr of evolutionary time, probed on Southern blots with purified V_{β} probes and the S107 V region. Evidence that the rate of divergence of V_{β} s is in fact greater than that of V_H s is indicated by the fact that in general the V_{β} probes only hybridize well with closely related rodent genomes^{36,37}. S107 V_H , on the other hand, hybridizes well with squirrel (60 Myr divergence)³⁷ and rabbit (70 Myr divergence)³⁶ on comparable blots. Furthermore, S107 V_H and an independent V_H probe, μ 107 V (discussed in ref. 38), have been shown to hybridize well in more stringent conditions to much more distantly related genomes³⁸, including the primitive reptile, *Caiman crocodylus* (300 Myr divergence from mouse³⁶). Murine V_{κ} probes have also been shown to cross-hybridize well on human genomic Southern blots³⁹. Taken together, these data indicate that most V_{β} s acquire mutations at a significantly greater rate than V_H s and V_{κ} s¹⁵. While Southern blots do not provide the resolution of sequence data, this observation is consistent with the notion that a greater portion of V_{β} s are devoted to interaction with variable determinants and are thus selected to be hypervariable.

Fig. 5 Secondary structure predictions. The algorithm of Chou and Fasman⁴² was used to predict the locations of probable β -sheets and turns in the V_{β} sequences and in representative immunoglobulin sequences²⁵. P_{β} , plotted on the vertical axis, represents the β -sheet conformational parameter as defined⁴². Arrows are centred on regions of sequence where $P_T > P_{\beta}$ and $p_T > 0.75 \times 10^{-4}$. In regions where turns were predicted to be directly adjacent or to share amino acids, only the most probable turn is indicated by an arrow.

Consistent with an increased rate of divergence is the fact that four of the five V_{β} regions hybridize to single bands in the genome compared with between 4 and 30 bands that are observed with V_H ⁴⁰ and V_{κ} ^{39,41} probes. That we see single hybridizing bands does not rule out the possibility that there are families of related V_{β} sequences; it suggests, rather, that members of a given family have probably diverged too much from each other to cross-hybridize at the relatively moderate stringencies used here. The exception to this rule, C5, lends support to the above interpretation. It is the only V region that is conserved enough between species to hybridize well to squirrel, rabbit and human genomic DNAs, consistent with the observation that it is also the only V region to hybridize to multiple bands in the species surveyed³⁻⁸. The simplest interpretation of these hybridization patterns is that variation in some V_{β} sequences is under more stringent constraints than others, and that such V_{β} regions will therefore have retained enough sequence homology between duplicated copies in a given genome to appear as gene families. It also suggests that very low-stringency hybridization experiments may reveal that some of the other V_{β} sequences are also members of homologous gene families.

Homology with immunoglobulin

Based on amino acid homology, the published sequence of 86T1 more closely resembles a variable region from a κ chain (McPC 603, 33 of 84 amino acids homologous) than a variable domain from either a λ (MOPC 104e, 25 of 86) or heavy chain (93G7, 26 of 90)². Each of the additional V_{β} s reported here is more

Fig. 6 Possible T-cell receptor structure and implications for recognition. *a*, An α -carbon skeleton of the X-ray crystallographic structure of McPC 603 (ref. 43). Thick lines denote heavy-chain residues. Closed circles correspond to classical hypervariable residues. The regions of sequence identified in Fig. 3*B* (A, C, E, F) that correspond to V_k framework regions, but are significantly more variable in V_β s, are shown as solid bars. *b*, A schematic diagram of antibody-antigen (Ag) interaction; *c*, *d*, models of T-cell receptor binding.

homologous with this κ V region than with these λ or heavy chains. Among the conserved residues that form the interface between V_H and V_L ⁴³, the T-cell receptor conserves the same amino acids at more of the light-chain contact residues (Tyr 36, Gln 38, Leu 46) than those of heavy chain (Gln 39, Leu 45). By these criteria, V_β most resembles a κ variable region. The only structural features which are more heavy chain-like are the number of amino acids from the invariant tryptophan to the last cysteine of the V region (4 or 5 residues shorter in V_κ than in V_β) and the fact that the last V_β framework region extends several amino acids past this cysteine, as in V_H . These similarities of V_β to V_H at the carboxy-terminal end may relate to the presence of D region elements^{4,5} and to the larger J regions characteristic of heavy chains^{4,6}. The intron-exon structure of the constant region with its separate hinge and transmembrane regions is also more heavy chain-like⁶.

Despite the similarities in amino acid sequence between V_β and V_κ , the relative lack of primary structure conservation among V_β s makes it important to determine whether the predicted secondary structure of these V_β s differs significantly from the known structure of V_κ and whether secondary structure is predicted to be conserved among V_β s. We therefore used the empirically derived algorithm of Chou and Fasman⁴² to locate regions of sequence predicted to be probable β -sheets or β -turns. We assumed that V_β s, like V_H and V_κ , have little or no α -helical content. Figure 5 shows the β -sheets and turns predicted by the algorithm of Chou and Fasman for six of the seven V_β s reported here. The predicted secondary structures of representative heavy- and light-chain V regions are included for comparison.

This analysis reveals that, among these V_β s, seven β -sheets are consistently predicted (five of six or better) in regions of sequence that correspond to β -sheets in immunoglobulin. The only apparent departure of the V_β predicted secondary structure from the known immunoglobulin structure is in residues 65–69 whose V_κ counterparts are known to comprise a β -sheet, but are predicted to be a sheet in only one of six V_β s (E1). The lack of a β -sheet in this region of sequence has precedent in immunoglobulin, as the Chou–Fasman algorithm often fails to predict the corresponding sheet in κ (unpublished observation). Thus, despite the extreme variability in primary structure between V_β s, the secondary structure is predicted to be conserved and to be immunoglobulin-like.

Models of T-cell receptor binding

Because of the similarities in the primary and predicted secondary structure between the T-cell receptor and the extensively characterized immunoglobulins, it is instructive to ask where, by analogy with immunoglobulin, putative new V_β hypervariable regions lie on the molecule. Historically, the assumption that regions of sequence which are highly variable among many immunoglobulins correspond to portions of the molecule which make physical contact with antigen has been a useful principle in analysing the antigen-binding site of immunoglobulins¹³. We have therefore applied this heuristic to the T-cell receptor β -chain in order to derive the implications for antigen–MHC interactions from the predicted location of putative new HV regions. Adapted from ref. 43 is an α -carbon skeleton of an immunoglobulin Fab from the myeloma McPC 603. Classical hypervariable regions are indicated on this Fab model by closed circles; regions of V_κ that correspond to putative new V_β hypervariable regions are indicated by heavy bars. Regions A and F correspond to external loops between antiparallel β -sheets, as do classical immunoglobulin HV regions. Region E corresponds to a β -turn and sheet that interacts with solvent in the V_κ molecule. Curiously, these regions lie external to the classical immunoglobulin antigen-binding site. Their variability in V_β suggests that important interactions may be occurring on the outer surface of the receptor, perhaps with polymorphic histocompatibility determinants. Region C corresponds to a β -turn and sheet that is highly conserved at the amino acid level in V_κ and makes multiple hydrophobic interactions and hydrogen bonds with the immunoglobulin heavy chain⁴³. In the T-cell receptor, despite the greater variation in amino acid residues in this region, the secondary structure is predicted to be highly conserved (Fig. 5). Although based on a small number of sequences, the variability of these residues in V_β suggests that they interact with solvent, antigen or the MHC; alternatively, the other chain of the T-cell receptor (α) has complementary variability in the residues in contact with this region of V_β .

Present cellular evidence indicates that a single T-cell receptor is responsible for recognizing both MHC and antigenic determinants^{44–46}. Assuming that the binding site(s) of this receptor consists of the α - and β -chains and that they fold in an approximately immunoglobulin-like fashion, the localization of the putative new hypervariable regions (Fig. 6*a*) suggests that the T-cell receptor may have the properties shown schematically in Fig. 6*c*, *d*. Specifically, it may have a larger binding pocket than that of immunoglobulin and its outer surface may be in contact with polymorphic MHC determinants. An alternative model (not shown) proposes the interaction of MHC with the classical immunoglobulin-like binding site, and antigen interacting with the putative new HV regions on the outer surface of the receptor. These models predict that different MHC restriction elements could alter the antigen-binding properties of the β -chain through allosteric effects. Preliminary evidence with anti-cytochrome *c*-reactive hybridomas is consistent with these models, as different β -chain V regions are used against the same antigenic peptide in the context of different MHC restricting alleles (S. Hedrick, unpublished observation).

The unidentified source of the γ -ray burst of 5 March 1979, GBS0526-66, may be located in the supernova remnant N49 in the Large Magellanic Cloud¹, though some authors^{2,3} have questioned the implied distance of 55 kpc. Among several unusual features of the source (reviewed by Cline⁴) is its repeatability: a total of 16 γ -ray bursts have been reported³, which may be periodic⁵. Only γ -ray bursts have been detected from this source. The situation for other γ -ray burst sources is not very different. Optical transients are known, in three cases^{6,7}, to have occurred near positions of later γ -ray bursts. Even so, no source has been identified optically⁸⁻¹⁰, and only upper limits are known for simultaneous emission of optical radiation with γ -ray bursts¹¹. Here we report that GBS0526-66 was monitored for ~910 h, using a high speed photoelectric photometer, attached to a 50 cm telescope at ESO/La Silla. Three short optical flashes were found, which may possibly be related to the γ -ray burst phenomenon. The most intense of these occurred on 1984 February 8 UT 07:42. It reached a maximum brightness corresponding to $m(\text{visual}) = 8.7$. The shape of the light curve bears remarkable similarity to the initial 200 ms of the 1979 March γ -ray burst.

Fig. 1 An event observed 1983 October 27 UT 01:28. The time bin is 4 ms. Vertical axis corresponds to no. of counts, uncorrected for dark count or sky.

Photometric observations of the 1979 March γ -ray burst error box were made during the period 1983 October 5 to 1984 February 23. A single channel photometer was used with a rectangular entrance diaphragm, 20 by 80 arc s, aligned with the error box. Offset-guiding allowed the diaphragm to remain centred on the error box during almost all the observations and, in particular, during the burst moments discussed here. Most measurements were done through a Johnson V filter ($\lambda = 550$ nm, $\Delta\lambda = 80$ nm). During the period up to 1983 October 20, an EMI 6256 photomultiplier was used; later data were acquired with an RCA C31034A tube. Pulse counts were written on magnetic tape at equal time intervals. The time bin was 4 ms until 1983 November 26, and 1 ms afterwards. Integrations with a time-base of 4 ms were kept in floating-point words; those of 1 ms were packed with two integers per 16-bit word. The resulting maximum count rate $255,000 \text{ s}^{-1}$ corresponds to $m(\text{vis}) = 6.6$. A strip-chart recorder allowed immediate inspection of the count rate. The observer could set the time resolution, usually 1 or 0.5 s. During part of the observations, an on-line burst detecting procedure informed the observer about possible bursts in order that the sky conditions could be checked. An atomic beam standard frequency clock was used for time keeping. Absolute

Fig. 2 An event observed on 1984 January 30 UT 03:20. The time bin is 1 ms.

time is presently known only to ± 100 ms because of an error in the calibration procedure. Data from 1983 November 2 to 19 were not recorded digitally, but only using the strip-chart recorder. The constancy of the system sensitivity was checked against the nearby star SAD249271, whereas photometric calibration was done using data from various E-region stars taken from ref. 12. The observations were carried out throughout the moon cycle, in spite of occasional light cloud cover.

A number of natural and man-made phenomena can cause spurious burst detection. Some, including electronic switching noise, lightning, the xenon flashlamps on aircraft, and meteors passing through the field of view, are of only millisecond duration, or less. We believe we have eliminated such effects by disregarding events lasting < 20 ms. Longer events, which may possibly mimic cosmic bursts, include the decay of luminescent meteor trains in the field of view, diffuse sky background illumination due to flaring fireballs, and the passage of artificial Earth satellites across the field of view. Little appears to be known about the first of these effects. Data published by Sekanina¹³, indicate that fireball light curves often have multiple maxima, and decrease in luminosity more rapidly than they increase, which is inconsistent with the events observed here. Slow-moving, artificial satellites would generally produce symmetrical light curves. Occasionally, a satellite may change brightness while moving only a few arcseconds, with unpredictable photometric results. Symmetric events of 32–90 ms duration have been observed on ten occasions, but we have not been able to demonstrate coincidence with a satellite passage. Finally we mention that Moon-illuminated clouds and contrails from jet aircraft can produce 'bursts' of a wide range of shapes and different durations. Contrails are particularly bothersome, as they may occur under all photometric conditions.

All data acquired during the 910 h observation period have been examined for the occurrence of highly significant events. The following three events comprise all flashes not suspected of being man-made, and of > 20 ms duration. Events discarded include the ten possible satellite passages, and a few chaotic events possibly attributable to low line-voltage. All three events were observed under perfect conditions—dark and clear sky; diaphragm well centred on error box. Their light curves are shown in Figs 1–3.

(1) 1983 October 27 UT 01:28 (Fig. 1): The burst was registered by the triggering routine. The two observers in the dome noted normal sky conditions. The rise time, half-width (FWHM) and total duration were < 4 , 8, and 90 ms, respectively. Maximum brightness was $m(\text{vis}) = 8.4$. The amount of energy in the first 4 ms time bin, relative to that in the tail, was $\sim 1/3$. This is possibly inconsistent with the detection of a meteorite passage, followed by the decay of its train. However, this explanation cannot be precluded. It is also possible that the rise time is in fact resolved: the bin preceding the maximum may indicate the start of the phenomenon. Alternatively it could be a statistical fluctuation.

(2) 1984 January 30 UT 03:20 (Fig. 2): The telescope was unattended. The rise time, half-width and total duration were

Fig. 3 An event observed on 1984 February 8 UT 07:42, at phase zero of the possible 164-day period determined by Rothschild and Lingenfelter⁵. The time bin is 4 ms.

3, 3, and 60 ms, respectively. The maximum brightness was $m(\text{vis}) = 9.9$.

(3) 1984 February 8 UT 07:42 (Fig. 3): The telescope was unattended. Maximum brightness was $m(\text{vis}) = 8.7$. The rise time, half-width and total duration were 110, 90 and 1,700 ms respectively. The event differs from the others by its much longer duration. Its resolved rising edge is a strong argument against a meteor explanation. The maximum brightness, integrated over the visible band, and referred to the top of the atmosphere, is $1.0 \times 10^{-9} \text{ erg s}^{-1} \text{ cm}^{-2}$. The corresponding fluence is $1.6 \times 10^{-10} \text{ erg cm}^{-2}$.

The simultaneous detection of γ -ray bursts and optical flashes would convincingly establish their cosmic origin. During our observations, four spacecraft with γ -ray detectors were in operation: ICE, PVO, SMM and Prognos 9. Preliminary analysis of these has revealed no response at the time of any of the optical flashes. The detector thresholds depend strongly on the time history and energy spectrum of a burst, but can be conservatively characterized by a fluence of $10^{-6} \text{ erg cm}^{-2}$, at energies above 100 keV. A pending analysis of real-time data may reduce this value by a factor of two. The absence of γ -ray burst detections is not surprising, given the thresholds and sensitivities of the satellites: none detected any of the soft, repeating bursts observed by the KONUS instruments. The inferred fluence ratio $E(\text{opt})/E(\gamma) > 1.6 \times 10^{-4}$ is consistent with similar, published data: Grindlay *et al.*¹¹ found the upper limit 10^{-3} for one particular γ -ray burst, which could not be detected optically, and Schaefer^{6,7} deduced values near 10^{-3} for the three historic, optical transients mentioned above.

In spite of the absence of γ -ray detections, several facts make the optical events remarkable: (i) Two of them have fast rise times and relatively slow decay, reminiscent of the 1979 March 5 event and of some of the recurrent bursts. (ii) The shape of the third burst is similar to the initial, impulsive phase of the 1979 March 5 γ -ray burst¹⁴. Both phenomena show a plateau at about half intensity, following the peak. The main difference is the finite rise time of the optical flash and its longer duration. (iii) The moment the third event occurred is consistent with the day of phase zero, as extrapolated from the formula given by Rothschild and Lingenfelter⁵: at this phase, a rather high burst rate may be expected.

We note that all published light curves of γ -ray bursts from GBS0526–66 (refs 1, 15–17) show very short rise times. If the 1984 February 8 optical flash represents reprocessed γ -rays from such rapid events, the rise time and half-width of the optical flash may be used to estimate a typical dimension of 30,000 km for the emitter. Unless the γ -ray bursts are strongly beamed, this seems to rule out reprocessing in the atmosphere of a (non-degenerate) neighbour star as proposed in the model of London and Cominsky¹⁸. However, it is consistent with small-disk models and with models involving cyclotron reprocessing. The latter have been considered by Woosley¹⁹.

We thank R. Lindskov-Simonsen and R. Castillo for help in making observations and data analysis; S. Laursen for work on hardware and software; the Danish Board for Astronomical

Research for a travel grant; and G. Andreoni for work with telescope tracking models.

Is Geminga a very close neutron star binary?

P. E. J. Nulsen & A. C. Fabian

Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge CB3 0HA, UK

Geminga (2CG195+4) is one of the brightest sources in the sky at photon energies around 1 GeV (refs 1-3). It has been tentatively identified⁴ with an unusual soft X-ray and optical object for which the γ -ray-to-X-ray-to-optical luminosity ratios are $\sim 10^6:10^3:1$, which may now have been confirmed by the discovery⁵ of a ~ 60 -s periodic variation in the X-ray source, similar to that reported in γ rays. The period has been increasing over the past 10 yr at a rate such that it doubles in ~ 400 -800 yr. The implied rotational energy loss would supply the γ -ray luminosity of Geminga if the spinning object were a neutron star at a distance of ~ 10 pc, consistent with the very low observed X-ray absorption. A lone pulsar with a spin period of ~ 60 s cannot spin down at the required rate. The observed period would need to be due to precession or some other process. We show here that the presence of a close neutron star companion provides a suitable mechanism. All neutron star binaries may evolve through a Geminga-like phase.

A non-corotating conductor orbiting in a pulsar magnetosphere creates a circuit in which currents may flow along the field lines and through the neutron star (compare with the unipolar inductor of ref. 6). The currents will be driven by, and will tap energy from, the rotation of the pulsar. The optical and X-ray luminosities of Geminga are so small that plausible candidates for a conductor are severely restricted. A normal stellar companion would have to orbit at too great a distance and an ionized accretion disk (compare with ref. 7) or a white dwarf would be too luminous. We consider here that the conductor is another neutron star with a weaker, opposed, magnetic field. The 60-s period is identified with the difference between the spin frequency, F , of the neutron star (primary; with the larger magnetic moment, $\mathcal{M}_1$) and the orbital frequency of the other neutron star (secondary of magnetic moment $\mathcal{M}_2$). This orbital period is several minutes.

The common flux between two opposed coplanar dipoles of separation a is

$$\Phi = \frac{\mathcal{M}_1}{a} \alpha (1 - \alpha)^2 \int_0^{2\pi} \frac{\cos \phi \, d\phi}{(1 + \alpha^2 - 2\alpha \cos \phi)^{3/2}} \\ = 3\pi\alpha^2 \frac{\mathcal{M}_1}{a} f(\alpha) \quad (1)$$

where $\mathcal{M}_2 = \alpha^3 \mathcal{M}_1$, $f(\alpha)$ varies smoothly from 0.85 to 1 as α varies from 1 to 0. Hereafter we adopt $f(\alpha) = 1$. The effective cross-section of the secondary ($3\pi\alpha^2 a^2$ for small α) may greatly

exceed its geometric cross-section. The structure of the magnetic field is outlined in Fig. 1. The maximum voltage around the generator circuit occurs between the pair of 'last common field lines' coplanar with the two dipoles and the rotation axis. By mapping the field lines onto the primary, we obtain for small α

$$V_{\max} = 2\sqrt{3} \alpha \mathcal{M}_1 (F - \sqrt{GM/a^3})/a \\ \approx 3.5 \times 10^{12} \alpha \mathcal{M}_{21} a_8^{-1} \text{ V} \quad (2)$$

where $M = (M_1 + M_2)$ is the mass of the system, $a = 10^8 a_8$ m and $\mathcal{M}_1 = 10^{21} \mathcal{M}_{21} \text{ T m}^3$. A magnetic moment $> 2.5 \times 10^{21} \text{ T m}^3$ takes the surface field beyond the quantum limit where spontaneous pair creation is expected. A further small voltage difference of $\frac{3}{2} \alpha^2 \mathcal{M}_1 \omega'/a$ can occur if the spin of the secondary deviates from corotation by ω' .

The current flow in the magnetosphere cannot produce magnetic fields in excess of the dipolar ones^{8,9}, which in the present case limits the total current to less than

$$I_{\max} \approx 2\pi\alpha \mathcal{M}_1 / \mu_0 a^2 \\ = 5.0 \times 10^{11} \alpha \mathcal{M}_{21} a_8^{-2} \text{ A} \quad (3)$$

Deep within the crust of a neutron star, the electrical conductivity is isotropic and extremely large, but it is anisotropic at the surface if the magnetic moment is large^{10,11}. This region dominates the effective stellar resistance. A crude upper limit is obtained by applying a value for the surface conductivity ($\sigma_1 \approx 10^9 \text{ S m}^{-1}$, ref. 11) to the whole star;

$$R_{\text{eff}} < \frac{4a}{3\pi\alpha^2 r_*^2 \sigma_1} \\ \approx 4 \times 10^{-10} \alpha^{-2} a_8 \Omega \quad (4)$$

where r_* is 10 km. Since

$$R_{\text{eff}} \ll R_{\min} \approx V_{\max} / I_{\max} \\ = \frac{\sqrt{3}}{\pi} \frac{\omega a}{c} Z_0 \quad (5)$$

where $\omega = F - \sqrt{GM/a^3}$ and $Z_0 = \sqrt{\mu_0/\epsilon_0}$ ($\approx 38 \Omega$) the current is self-limited in the magnetosphere.

The power dissipated in the magnetosphere

$$P_m \approx V_{\max} I_{\max} = 4\sqrt{3} \pi \alpha^2 \mathcal{M}_1^2 \omega a^{-3} \mu_0^{-1} \\ = 1.7 \times 10^{24} \alpha^2 \mathcal{M}_{21}^2 \omega_{-1} a_8^{-3} \text{ W} \quad (6)$$

where $\omega = 0.1 \omega_{-1}$. It can be heuristically derived as the rate of working of the magnetic stress in the common flux tube. P_m should equal the power associated with the spin-down of the primary neutron star

$$P_R \approx 3.2 \times 10^{24} \text{ W} \quad (7)$$

for a period derivative of $3 \times 10^{-9} \text{ s s}^{-1}$, mass of $1 M_\odot$ and moment of inertia of $6 \times 10^{37} \text{ kg m}^2$. We propose that the electric potential ($\sim V_{\max}$) accelerates particles that radiate the observed γ rays. Synchrotron and curvature radiation from 1 to 10 TeV electrons can produce γ radiation in the appropriate range. Whatever the emission mechanism, its efficiency for γ -ray production must be very high ($> 99\%$), comparable with that of the pulsed emission from the Vela pulsar¹². We note that the large opacity to pair production on the magnetic field prevents γ rays emitted near the neutron star poles from escaping¹³. Ignoring beaming, the observed flux¹⁻³ of $2.4 \times 10^{-12} \text{ W m}^{-2}$ requires Geminga to be at a distance of ~ 11 pc.

A completely charge-separated beam will limit the current to $< I_{\max}$, since the potential variation across a current beam made of electrons or ions alone is roughly $\delta V \approx I/\epsilon_0 v_D > IZ_0$, where the drift velocity $v_D < c$. To attain P_m , we require the maximum current to flow and thus nearly neutral beams. This is achieved if the incoming particles dislodge charges from the neutron star surfaces. Pair production by γ rays in the intense magnetic field near to the neutron star may also supply a substantial fraction of the current carriers¹³.

The flux tube is an ellipse at the primary of semi-axes of $\sqrt{3/2}\alpha\sqrt{r_*^3/a}$ and $\sqrt{3}\alpha\sqrt{r_*^3/a}$, and for the parameters that give P_R its area, $A_\Phi \approx 4.7 \times 10^4 \alpha^m a_8^{-1} \text{ m}^2$, where $m = +2$ and -1 on the primary and secondary respectively. If the X-ray flux is due to black-body emission, we derive an area of $\approx 5 \times 10^4 T_6^{-2} \text{ m}^2$, where $T = 10^6 T_6 \text{ K}$. The X-ray observations⁴ suggest that the black-body temperature $T_6 \approx 1$. The optical flux can also originate here; the precise optical-to-X-ray luminosity ratio depending on the observing windows but could be $\ll 10^{-3}$. Further emission may originate at the secondary and in the beams themselves. The work function of the surface is $\sim 1\text{--}10 \text{ keV}$ at the relevant magnetic field strengths¹⁰, so thermionic emission at the black-body temperature cannot supply the neutralizing charge, although there may be an optically-thin outer region heated to greater temperatures.

The γ -ray modulation is assumed to be due to variation in the magnetic field strength at the base of the common flux tube as it travels over the primary star, caused by misalignment of the rotation and magnetic axes and/or non-dipolar components of the field. The 60-s period is identified as $2\pi/\omega$ (see equation (5)). There are three independent frequencies in this system (two spins and the orbit) which could lead to great complexity in its periodic behaviour. In particular, the frequency of variation may be different in different wavebands, so that the period derivative from Bignami *et al.*⁵ could even be incorrect.

In order that $P_m \approx P_R$, the orbital separation of the two neutron stars, a , must be $\leq 10^8 \text{ m}$. If they are each of $1 M_\odot$, then the orbit will decay due to gravitational radiation in $\leq 30,000 \text{ yr}$. The power radiated by gravitational waves is $\approx 3 \times 10^{29} a_8^{-5} \text{ W}$ and exceeds that as electromagnetic radiation. In this model, Geminga is essentially a 'gravity wave binary'. The relative strain at Earth is $\approx 6 \times 10^{-20} a_8^{-1}$ and is unfortunately as yet undetectable¹⁴.

In view of the short anticipated life of Geminga, both to spin-down ($\sim 800 \text{ yr}$) and to gravitational radiation ($\approx 30,000 \text{ yr}$), it is important to consider its formation. Binary neutron stars may form in the Galaxy at a rate¹⁵ of $\sim 3 \times 10^{-4} \text{ yr}^{-1}$ with orbital periods of between one and a few hours. The *a priori* probability of the existence of such a neutron star binary within $\sim 100 \text{ pc}$ approaches one, as the lifetime to gravitational radiation is $\sim 10^7\text{--}10^8 \text{ yr}$. To observe it during a phase lasting $\leq 10^3 \text{ yr}$ and at a distance of $\sim 10 \text{ pc}$, however, makes Geminga exceptional.

Beaming of the γ -ray flux can relax the distance estimate. We also note that any model involving a rapidly-spinning neutron star in which the 60-s period is due to free precession and which spins down in $< 10^3 \text{ yr}$ dissipates $> 10^{30} \text{ W}$. It is then difficult to see how Geminga could be at a distance of $< 100 \text{ pc}$. A possible alternative interpretation in which the object is nearby would be that the $\sim 800 \text{ yr}$ time scale is due to change in distortion of such a pulsar with a weak magnetic field and spin period of $\sim 100 \text{ ms}$. The free-precession frequency is proportional to the difference between the principal moments of inertia. It is then a mystery as to why Geminga is not a radio pulsar⁴. The object would also be a strong source of gravitational waves.

After formation, a neutron star binary goes through a pulsar phase until the speed-of-light cylinder of the star with the greater magnetic moment passes beyond the orbital separation that is

$$F \leq c/a \quad (8)$$

After this phase the unipolar generator mechanism will take over control of the spin-down rate, so that from equation (6)

$$\frac{dF}{dt} = -\frac{4\sqrt{3} \pi \alpha^2 \mathcal{M}^2 (F - \sqrt{GM/a^3})}{\mu_0 \mathcal{J} F a^3} \quad (9)$$

where $\mathcal{J}$ is the moment of inertia of the primary. The spin-down has an insignificant effect on the orbit (because the orbital angular momentum always greatly exceeds that in the spin), so that the orbit decays due to gravitational radiation¹⁶ as

$$a = \left[a_0^4 - \frac{256 G^3 M_1 M_2 M}{5 c^5} t \right]^{1/4} \quad (10)$$

Fig. 1 Magnetic field of a pair of opposed coplanar dipoles. This shows some field lines (not equally spaced in flux) in the plane containing the two dipoles, for $\alpha = 0.5$ (see equation (1)). The boundary of the common flux tube, the 'last common field lines', is shown as bolder than the rest. The dashed circle separates the regions dominated by the two dipoles. The magnetic field is zero on a circle surrounding the weaker dipole where the last common field lines cross over. Although distorted, this feature remains when the dipoles are (moderately) misaligned and when currents $\leq I_{\max}$ flow. There are large potential differences across the boundary of the common flux tube, particularly near the cross-over points where the two regions of isolated field come into contact.

from the initial separation a_0 . While the spin frequency, $F \gg$ the orbital frequency, $\sqrt{GM/a^3}$, equations (9) and (10) may be combined to give

$$(1 - F/F_0) \approx \Gamma(1 - a/a_0) \quad (11)$$

where F_0 is the initial spin frequency, and

$$\Gamma \approx 210 \alpha^2 \chi^2 / \xi a_0^2 \quad (12)$$

where $a_0 = 10^9 a_9 \text{ m}$, $F = \xi c/a_0$ (compare with equation (8)), the polar magnetic field on the primary is

$$B_1 = \chi m_e^2 c^2 / \hbar = 4.7 \times 10^9 \chi \text{ T} \quad (13)$$

and the primary and secondary stars have both been given the parameters adopted above. The remarkable feature of equation (12) is that for reasonable values of the parameters $\Gamma \sim 1$. The binary orbit thus decays at a comparable rate to the spin of the primary. Failing this condition, either the orbit would decay without any significant spin-down ($\Gamma \ll 1$; mostly spin-up) or the spin-down would bring the primary close to corotation before the orbit decayed significantly ($\Gamma \gg 1$). (It is possible that the system did start with $\Gamma \ll 1$, but in that case the gravitational decay time now must be very short indeed, $\ll 800 \text{ yr}$, and the primary star must have started with a spin period $\approx 60 \text{ s}$.) The required high magnetic moment of the primary neutron star implies that it cannot be very old ($\leq 10^7 \text{ yr}$) if current ideas¹⁷ on the decay of magnetic fields are correct.

There is an alternative to the above evolutionary picture which can also produce the Geminga system. The unipolar generator is self exciting once a substantial current has been established because this heats the foot of the flux tube as discussed above. However, if there is very little matter in the magnetosphere the currents may not be able to turn on spontaneously. Perhaps the event¹⁸ of AD 437 was associated with the start of the current flow, caused by accretion of matter passing through the system or by a crustquake¹⁹.

The final outcome of the close neutron star binary we have proposed for Geminga is uncertain²⁰, but it could be a black hole or a millisecond pulsar¹⁵.

We thank K. A. Arnaud, G. F. Bignami, D. O. Gough, E. Priest, J. E. Pringle and M. J. Rees for discussions.

Is Cygnus X-3 a monoenergetic 10^{17} eV accelerator?

A. M. Hillas

Physics Department, University of Leeds, Leeds LS2 9JT, UK

Like many other X-ray sources, Cygnus X-3 seems to be a binary system that includes a compact object, but it is unusual in being enshrouded in gas, in displaying occasional huge outbursts and in emitting much more energy above 10^{11} eV than in the keV X-ray region. If the compact object is a pulsar, the ultra-high-energy photons can be products of an accelerated beam of protons (or nuclei) striking the companion's atmosphere^{1,2}. It is noted here that a roughly monoenergetic spray of $\sim 10^{17}$ eV protons at $\sim 10^{39}$ erg s⁻¹, generating an electron-photon cascade in the environs of the companion star, best accounts for all photons above a few GeV, and might generate the gas shroud, as beam energy deposition inside the star could lift off a thick layer of matter to generate a fountain under the pulsar. This evidence on the nature of the accelerated beam is particularly significant as Cygnus X-3 seems likely to be responsible for most of the cosmic ray particles around 10^{17} eV which are at present being injected into the Galaxy.

γ Rays are seen briefly at two portions of the 4.8-h binary period, at phases reported variously as 0.15–0.25 and 0.63–0.8, taken from the time of deepest eclipse of the X-ray source; the spectrum extends (roughly as $E^{-2} dE$, where E represents energy) to 10^{16} eV (refs 3, 4). Vestrand and Eichler^{1,2} have suggested that we see the pulsar through the tenuous outer layers of the companion just before and after eclipse, and see photons from nuclear interactions (via π^0 decay) in the gas. This is supported by the finding that although a potential drop of 10^{17} V required to accelerate charged particles could hardly be found more than ~ 100 km from the pulsar, the 10^{16} eV photons cannot penetrate a transverse magnetic field exceeding 500 G (ref. 5) and hence must be formed far away, somewhere near the companion star ($\sim 5 \times 10^{10}$ cm distant), where the field is believed to be of this magnitude^{5,6}. However, three problems arise: (1) The diameter of the relevant outer surface of the companion must be very large¹, as it appears to eclipse the source of X rays and low-energy γ rays for $\sim 40\%$ of the orbit. Modelling of the intensity curves⁷ indicates that the shadow must be cast by gas present far outside any plausible Roche lobe of the companion unless the pulsar is extraordinarily light. (2) How is the spectrum generated? (3) How do the 10^{12} eV photons remain well collimated if they are derived from 10^{13} eV protons, as has generally been supposed? To explain radio emission, Vestrand⁶ requires a magnetic field (B) of 500–1,000 G to be embedded in the gas, and Stephens⁴ showed that such a field could cause the sharp end to the photon spectrum. The radius of gyration of 10^{13} eV protons would then be less than 10^{-2} of their path either before or after entering the gas, destroying all directionality. I will initially assume that this local field is present, but even if instead the only field arises from the pulsar, one still expects deflection

Fig. 1 Calculated photon spectrum resulting from cascades initiated by 10^{17} eV protons in gas surrounding the companion star (magnetic field present), for cases where integration extends to maximum gas thickness 1, 2 and 4 radiation lengths. Magnetic pair production⁵ causes the drop at 10^{16} eV. The dip starting at 10^{14} eV is due to pair production on primeval photons, assuming 12 kpc distance. The dotted line represents a non-magnetic cascade, initiated by 5×10^{16} eV protons (integrated to a maximum thickness of 16 radiation lengths). Data: Δ , ref. 19; $\blacktriangle$, ref. 20; $\diamond$, ref. 17; $\blacksquare$, ref. 18; ∇ , ref. 21; $\blacktriangledown$, ref. 22; $\square$, ref. 23; $\circ$, ref. 3; $\bullet$, ref. 4.

of protons from their regular streaming when this regular guiding field is distorted on meeting the gas.

As the pulsar enters eclipse, we must see it through successively greater thicknesses of gas, and hence should see an electron-photon cascade emerging. Figure 1 shows the time-averaged photon spectrum generated by a monoenergetic 10^{17} eV proton beam, assuming that the duration of viewing through different column densities μ of gas varies as μ^{-1} (as in an exponential atmosphere), although this is not critical. The density is typically $\sim 4 \times 10^{-9}$ g cm⁻³, and if there is an embedded field > 10 G, the cascade develops by alternate pair production and very rapid synchrotron radiation rather than by normal bremsstrahlung (and there is little contribution from column densities exceeding 2–4 conventional bremsstrahlung radiation lengths of ~ 40 g cm⁻²). A photon of energy E_γ eV is typically radiated by an electron of energy $E_e = 5.5 \times 10^9 (E_\gamma/B)^{1/2}$ eV (B in gauss). (Alternatively, without a local magnetic field, normal bremsstrahlung dominates: the ultimate spectrum and energy requirements are virtually the same, but more radiation lengths are required, partly because E_γ then falls as E_e rather than E_e^2 . The dotted line in Fig. 1 shows how the photon spectrum then terminates, for monoenergetic 5×10^{16} eV protons.) By choosing the flux of 10^{17} eV protons to fit the photon flux⁴ around 10^{15} eV, it accounts for the 10^{12} eV photons also: there is little room for additional production by protons below 10^{16} eV. With 10^{17} eV protons and a synchrotron cascade, there is no collimation problem. The 10^{12} eV photon is radiated by a 2×10^{14} eV electron (if $B = 500$ G) which suffers negligible deflection in travelling its typical radiation mean free path $10^7/(E_{14}B^2)$ cm, and the direction of the original 10^{17} eV proton is maintained. (There will, nevertheless, be a few widely spread photons, arising from muons which decay after many magnetic gyrations.)

The accelerated beam need not be strictly monoenergetic; we require the energy carried by protons above 5×10^{16} eV to be greater than that carried by protons in the four decades of energy below this, which can also contribute to the TeV photons, and the beam energy could be higher than 10^{17} eV, especially if hadron interactions greatly change⁸ at energies beyond the range explored by accelerators and fitted by the interaction model. Nuclei of the same energy per nucleon are permitted.

Fig. 2 Binary system, showing approximate directions to the observer when γ -ray bursts are observed (A, phase ~ 0.2 ; B, phase ~ 0.75), and fountain of ejected matter.

To give the flux shown in Fig. 1, the energy in the proton beam above 10^{16} eV must be $2 \times 10^{39} (\Omega/4\pi)(0.05/\Delta) (D/12 \text{ kpc})^2 \text{ erg s}^{-1}$, where D is the distance to Cygnus X-3, Ω is the solid angle into which the overall proton beam is emitted, and Δ is the duty cycle of one photon pulse at high energies (which may be as small as 0.02 (refs 3, 4)). Thus, the power L_p in the particle beam is about $10^{39} \text{ erg s}^{-1}$. Most of the protons (or nuclei) will escape into the Galaxy, providing $\sim 10^{39} \text{ erg s}^{-1}$ above 10^{16} eV per nucleon, and little of significance below this energy.

Wdowczyk and Wolfendale⁹ have already pointed out that about 30 Cygnus X-3s might supply the power to maintain the Galaxy's cosmic rays; but in the energy range above 10^{16} eV, one finds a more remarkable situation. How much power is required to maintain the galactic cosmic rays above 10^{16} eV against leakage? A transport model¹⁰ indicates a lifetime in the galactic disk (say 15 kpc radius and 0.6 kpc thick) of around $2.5 \times 10^5 \text{ yr}$ at this energy, which is also compatible with the lifetime of $>10^6 \text{ yr}$ at 10^{14} eV suggested by Kiraly *et al.*¹¹. Their local energy density $\sim 3 \times 10^{-17} \text{ erg cm}^{-3}$ would then require a power of $\sim 5 \times 10^{37} \text{ erg s}^{-1}$. Alternatively, one can use the variation of anisotropy with energy to estimate¹² the energy spectrum emerging from galactic sources to be $\sim E^{-2.47} dE$ particles s^{-1} (rather like the lower-energy source spectrum $E^{-2.44} dE$ of heavier nuclei deduced from spallation¹³). In this case, $\sim 5 \times 10^4$ of all injected cosmic ray energy goes into the particles above 10^{16} eV, that is, $2.5 \times 10^{37} \text{ erg s}^{-1}$. Hence, the Galaxy's needs are evidently $\leq 10^{38} \text{ erg s}^{-1}$ averaged over 10^5 yr , and sources like Cygnus X-3 can be present only for a part of this time interval. It is therefore unlikely that any other such objects exist in the Galaxy. (The source Vela X-1 is only $\sim 10^{-2}$ as powerful¹⁴.) If the source emits a monoenergetic spectrum, it is normally assumed that one must rely on evolution of beam energy with time to generate the observed spectrum of galactic cosmic rays¹⁵. Cygnus X-3 might, of course, be less powerful than assumed if its pulsar is an aligned rotator, only firing its protons towards us (small solid angle Ω).

Where it strikes the star directly, the beam will deposit $\sim 40\%$ of its energy in an electron-photon cascade at depths 100–500 g cm^{-2} . Here, at $z \sim 100$ Thomson scattering mean free paths below the surface, the thermal leakage time is long, and it will generate a pressure $0.5 L_p z / 4\pi d^2 c$ (if the absorbing layer is at a distance d from the pulsar), z times the direct pressure of the beam. This will easily lift off the overlying few hundred g cm^{-2} if $M_{\text{star}} \sim (0.3-3) M_{\odot}$, and should be far more effective than keV X-ray absorption in ejecting matter. (The mechanical work done in removing $2 \times 10^{-3} M_{\odot} \text{ yr}^{-1}$ —taken as an upper limit⁶—is $< 10^{38} \text{ erg s}^{-1}$.) Nearby surface matter must therefore be lifted off, and a fountain of gas under the pulsar may normally cushion the main body of the star from catastrophic ejection. Although the gas dynamics will be complex¹⁶, a rough idea of the possible disposition of gas is suggested in Fig. 2, based on trajectories of independent particles emitted at up to the escape velocity,

and influenced by a slightly super-eddingtonian radiation pressure from the pulsar. Rotation of the system is responsible for the asymmetry, and the pattern roughly reflects the actual direction from which γ -ray pulses are reported. The large size of the occulting body may arise in this way. Dowthwaite *et al.*¹⁷, however, report a 10^{12} eV signal at phase as early as 0.63, when the pulsar is presumably well in front of the companion. A small X-ray spike is often seen at this point, and as the pulsar is probably plunging in towards periastron near here⁷, it may become embroiled with the gas at this moment. The 34-day variation may be related to a lag in rotation of the companion, along with its magnetic dipole, as this may affect the gas flow.

A requirement of this model is that the 10^{15} eV γ -ray burst should be slightly offset in time (by about half the burst duration—say 0.02 cycle) from the 10^{12} eV γ rays, which require more matter for their production (TeV photons earlier at the 0.2 phase). This may be the case^{4,18}, but there has been uncertainty in the synchronization of phases between different workers, observing over different periods, and it would be desirable to test this by measuring the relative timing of pulses of high and lower energy over the same interval. The 0.7-phase burst may fluctuate somewhat in position, and if so, the start of the sharp intensity drop in X rays should remain synchronized with this γ -ray burst.

Rising atmospheric carbon dioxide concentrations may increase streamflow

S. B. Idso* & A. J. Brazel†

*US Water Conservation Laboratory, 4331 East Broadway, Phoenix, Arizona 85040, USA

†Laboratory of Climatology, Arizona State University, Tempe, Arizona 85287, USA

Historically, studies of the greenhouse effect of carbon dioxide (CO_2) have dealt primarily with temperature and only secondarily with precipitation. In the latest report on this topic¹, however, the subject of streamflow is broached with an analysis² which suggests that watersheds in the western United States will suffer 40–75% reductions in streamflow for a doubling of the atmospheric CO_2 content, leading to a 2°C rise in air temperature and a 10% drop in precipitation. A shortcoming of that study is that it does not include the direct antitranspirant effect of atmospheric CO_2 enrichment that would accompany any CO_2 -induced climatic change, whereby increasing CO_2 content of the air tends to induce partial stomatal closure, so reducing plant transpiration and thereby

conserving soil moisture and increasing runoff to streams. Inclusion of this latter effect in a simple model of watershed runoff applied to 12 drainage basins in Arizona indicates that 40–60% increases in streamflow may well be the more likely consequences of a CO₂ concentration doubling, even in the face of adverse changes in temperature and precipitation.

To ensure valid comparability with the National Research Council (NRC) study¹, we used the identical model employed by them to estimate changes in runoff induced by changes in temperature and precipitation and then superimposed the anti-transpirant effect of atmospheric CO₂ enrichment on those results. Thus, we will first briefly describe that model. Table 1 represents a set of empirical relationships among temperature, precipitation and runoff derived by Langbein *et al.*³ for relatively arid areas in the western United States. Our first step was to confirm that this tri-factor matrix used by Revelle and Waggoner² did indeed apply to the 12 Arizona drainage basins we selected for study, which are described in detail elsewhere⁴. Thus, we first derived mean annual values of surface air temperature and precipitation from a report⁵ which gave this information at grid points distributed at spacings of 16 km, and used the results to calculate watershed runoff by this method. Then, from another report⁶ which gave the long-term (30–50 yr) mean annual runoff of the 12 drainage basins as directly measured by stream gauges, we extracted data to use as a standard for comparison. This exercise yielded the plot of Fig. 1, where it can be seen that the Langbein model does indeed adequately describe the mean annual runoff of the 12 Arizona drainage basins selected for study.

We next used the Langbein model of Table 1 in a manner analogous to that of the NRC study to determine the effects of possible CO₂-induced changes in climate. The scenarios we considered were: first, the same 2 °C rise in temperature and 10% drop in precipitation investigated by the NRC report authors; second, a 2 °C rise in temperature with no change in precipitation; and third, a 10% drop in precipitation with no change in temperature. Mean percentage decreases in streamflow for the five wettest basins derived for these scenarios were, respectively, 41, 23 and 23%, with some of the drier basins actually suffering 100% reductions and ceasing to provide any streamflow whatsoever. Up to this point all the results accord with those of Revelle and Waggoner².

Following the lead of the NRC report, we next expressed

Table 1 Mean annual runoff (mm yr⁻¹) as a function of mean annual temperature (°C) and mean annual precipitation (mm yr⁻¹) for the arid southwestern United States

Temperature	Precipitation					
	200	300	400	500	600	700
-2	54	92	154	230	330	440
0	40	74	124	190	275	380
2	28	57	95	154	225	320
4	17	40	78	125	190	265

runoff (R) as the difference between precipitation (P) and evapotranspiration (E), setting $R = P - E$. Knowing R and P , we could thus solve this equation for E for current conditions, as well as for the three climate change scenarios previously described, and for each of the 12 drainage basins. Then, making use of the experimentally-documented fact that plant evaporative water loss is generally reduced to about two-thirds of its original rate by a doubling of the atmospheric CO₂ content^{7,8}, we adjusted each of these evapotranspiration results to reflect what they would be with the antitranspirant effect of atmospheric CO₂ enrichment superimposed on them. In doing this, however, it was necessary to express the adjusted evapotranspiration (E_a) as $(1 - 1/3 f)E$, where f represents the fractional area of the drainage basin covered by vegetation, as none of the basins was completely covered with plants. Thus, if there were no vegetation ($f = 0$) there would be no vegetative effect and E_a would equal E , whereas if the entire watershed were covered with vegetation, ($f = 1$), E_a would equal $2/3 E$. Our evaluations of f for this purpose were made from detailed descriptions and photographs of the 12 basins associated with the most recent vegetation maps of the area⁹. Values of f obtained by this method varied from a low of 0.24 to a high of 0.61, with an average for the five wettest basins of 0.49.

Following this procedure to obtain E_a values for each of the

Table 2 Mean annual observations and calculations of runoff for the five wettest basins studied for several climate change scenarios

Basin no.	Vegetation fraction	Observations			Calculated runoff							
		Mean annual T (°C)	Mean annual P (mm)	Mean annual R (mm)	Without vegetation effect			With vegetation effect				
					+2°-10% (mm)	+2°-0% (mm)	+0°-10% (mm)	+2°-10% (mm)	+2°-0% (mm)	+0°-10% (mm)	+0°-0% (mm)	
4906	0.61	9.3	627	111	78	101	105	177	203	198	215	
4940	0.57	9.3	607	105	69	91	97	160	188	183	200	
4985	0.42	11.3	559	70	46	56	53	109	126	115	138	
4990	0.41	12.6	588	74	38	49	58	105	129	122	143	
5053	0.45	11.9	562	108	43	62	51	112	128	119	176	
Mean	0.49	10.9	589	93	55	72	72	132	155	147	174	

Basin no.	% Change from observed							
	Without vegetation effect			With vegetation effect				
	+2°-10%	+2°-0%	+0°-10%	+2°-10%	+2°-0%	+0°-10%	+0°-0%	
4906	-30	-9	-5	+59	+83	+78	+94	
4940	-34	-13	-8	+52	+79	+74	+90	
4985	-34	-20	-24	+56	+80	+64	+97	
4990	-49	-34	-22	+42	+74	+65	+93	
5053	-60	-43	-53	+4	+19	+10	+63	
Mean	-41	-23	-23	+42	+67	+58	+87	

+2°-10% = 2 °C rise in temperature with a 10% reduction in precipitation.

+2°-0% = 2 °C rise in temperature with no change in precipitation.

+0°-10% = no change in temperature with a 10% reduction in precipitation.

+0°-0% = no change in either temperature or precipitation.

Fig. 1 Mean annual runoff from 12 Arizona drainage basins calculated by the Langbein model of Table 1 compared with measured mean annual runoff.

12 basins for the four scenarios under consideration (three climate change scenarios and one no-change situation), we next used these results to evaluate adjusted runoff (R_a) values which incorporated both the effects of the selected climatic changes (or non-change) plus the direct antitranspirant effects of a CO_2 concentration doubling. The results of this process, summarized in Table 2, indicated that for the first climate change scenario, that is, the 2°C rise in temperature and 10% drop in precipitation predicted in the NRC study, the mean change in streamflow of the five wettest basins calculated to accompany a doubling of the atmospheric CO_2 content went from -41% to $+42\%$ when the antitranspirant effect of the atmospheric CO_2 enrichment was added to the climate change effect. Similarly, when the vegetative effect of CO_2 was added to the climate change effect of the second scenario—a 2°C rise in air temperature with no change in precipitation—the mean change in streamflow of the five wettest basins went from -23% to $+67\%$. And for the third scenario—a 10% drop in precipitation with no change in temperature—it went from -23% to $+58\%$; while for the case of a negligible CO_2 effect on climate, it went from the status quo to $+87\%$. In all of these situations, we note that streamflow increases for the drier basins were of the order of several hundred percent.

We note also that our results are comparable with those recently obtained by Aston¹⁰ with a distributed deterministic process model used to simulate the effects of changed stomatal resistance on streamflow in Australia. Indeed, Aston concluded that “we can expect streamflow to increase from 40 to 90% as a consequence of doubling the atmospheric CO_2 concentration”, in what could also be a statement of our conclusions.

There are several simplifications and uncertainties associated with the above analysis which preclude its being accepted as the final word on the subject. For one thing, the fractional area of vegetation (f) is difficult to assess very accurately. In addition, it could well increase significantly in a CO_2 -enriched world¹¹, and it is likely that an unvegetated area will provide more runoff than a vegetated area of equal size. Also, a small infiltration component of the total water balance is neglected in both our analysis and that of Revelle and Waggoner². Both studies additionally suffer from lack of monthly resolution, and both fail to account for shifts in the time of major watershed runoff which may (or may not) occur as climate changes (or remains the same¹²). However, because both studies have about the same degree of complexity, the very opposite results which they produce illustrate that we are still at the stage where plausible additions to state-of-the-art model studies of the CO_2 ‘problem’

can dramatically alter current preceptions of future consequences.

Nd evidence for Proterozoic crustal development in the Belt–Purcell Supergroup

C. D. Frost* & R. K. O’Nions

Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK

A knowledge of the chemical and isotopic characteristics of the continents as they existed in the past is essential to an understanding of their evolution^{1–7}. Vestiges of these characteristics remain in the sedimentary record. For example, the character and crustal residence age⁴ of ancient continental crust has been deduced from the Sm–Nd isotopic patterns of clastic sediments that have survived to the present day^{4,6,8}. We report here Sm–Nd isotopic measurements from the Belt–Purcell Supergroup of western North America which form the first detailed isotopic investigation of a major Proterozoic sedimentary succession. The Belt–Purcell has many features also seen in the detrital load of the world’s major contemporary rivers, including exceptionally homogeneous $^{147}\text{Sm}/^{144}\text{Nd}$ and $^{143}\text{Nd}/^{144}\text{Nd}$ ratios and a small range of crustal residence ages. Mantle additions to the continental crust seem to have been relatively minor since the middle Proterozoic.

The Belt–Purcell Supergroup of the northwestern United States and southwestern Canada is the most extensive and least disturbed succession of Proterozoic sediments in North America. It outcrops over an area greater than 125,000 km^2 in western Montana, northern Idaho, southwestern Alberta and southern British Columbia (Fig. 1), and lies on ≥ 1.7 Gyr crystalline basement^{9,10}. Shallow water structures predominate throughout the succession^{11–15}. The time of deposition of the supergroup is uncertain, but may have spanned an interval of 1,500–1,200 Myr^{10,16–18}. Unconformably overlying the Belt–Purcell Supergroup are the impure clastics of the Windermere Supergroup, deposited around 800–600 Myr^{15,19}.

Proposed explanations for the depositional environment of the Belt–Purcell Supergroup include deposition in a miogeocline or within an adjacent failed arm of a rift system, and suggestions that Belt–Purcell deposition coincided with incipient rifting of a western continent, of entirely epicratonic deposition^{15,20–24}. Sediment source areas have been tentatively identified to the east, south and south-west of the Belt–Purcell deposit^{12,15,25,26}. However, Mesozoic listric thrust faulting within the Belt–Purcell basin involved translations of up to 180 km ¹¹ and thus hampers attempts to elucidate the original basin configuration, sediment

* Present address: Department of Geology and Geophysics, University of Wyoming, Laramie, Wyoming 82071, USA.

source directions or source areas. Information from Sm-Nd isotopes obtained from Belt-Purcell sediments may provide new insights into these problems, as well as into Proterozoic crustal development.

Samples have been selected mainly from two localities, one in the Purcell Mountains, British Columbia, and the other from the vicinity of the Whitefish Range, Montana (Fig. 1). We also analysed a sample from the Horseshoe Creek Group of the Windermere Supergroup. Exact sample locations and stratigraphic positions are described elsewhere²⁷.

Table 1 gives Sm-Nd isotopic measurements on these samples. Analytical procedures used follow those reported previously²⁸. Present-day $^{143}\text{Nd}/^{144}\text{Nd}$ ratios for Belt-Purcell rocks fall within a restricted range of 0.511615 ± 18 to 0.512040 ± 22 ($\epsilon_{\text{Nd}} = -20$ to -12) and $^{147}\text{Sm}/^{144}\text{Nd}$ ratios vary only from 0.099 to 0.120, even though Nd and Sm concentrations vary by a factor of 3–4. These $^{147}\text{Sm}/^{144}\text{Nd}$ ratios are typical of those reported for modern river sediments²⁹ and other fine-grained clastic sedimentary rock^{5,6,8}.

The uniformity of $^{143}\text{Nd}/^{144}\text{Nd}$ ratios for sediments deposited throughout a ~20-km thick succession during a period that may extend over some 300 Myr is striking (Fig. 2a). This constant isotope ratio probably indicates the presence of a particularly homogeneous and persistent sediment source, and/or very thorough mixing of a number of source materials over a period of several hundred million years. Crustal residence ages, which are calculated on the assumption that the Sm/Nd ratios of the sediments are unchanged from the time that their precursory continental material was generated by magmatic processes, are also uniform for the Belt-Purcell sediments, and with one exception fall between 1.9 and 2.1 Gyr (Table 1, Fig. 2b). The mean crustal residence age of the uniform source of sediment is well in excess of the depositional age and new mantle additions to the continent within the Belt-Purcell source area, over the interval concerned, are too small to be recognizable. The one sample which possesses a somewhat younger crustal residence age of 1.6 Gyr presumably reflects a larger than average additional contribution from a relatively young and probably locally supplied source.

It is useful to compare crustal residence and depositional ages of Belt-Purcell sediments with published results for Archaean sediments. The crustal residence age for Belt-Purcell samples

Fig. 2 a, $^{143}\text{Nd}/^{144}\text{Nd}$ plotted with respect to approximate stratigraphic ages for Belt-Purcell sediments. Stratigraphic ages are inferred from palaeomagnetic data¹⁶. b, Crustal residence age estimates (T_{CR}) plotted with respect to approximate stratigraphic age (T_{STRAT}) for Belt-Purcell sediments. c, Crustal residence age estimates (T_{CR}) plotted with respect to approximate stratigraphic age (T_{STRAT}) for Dalradian Supergroup samples. Comparison of b and c illustrates that whereas the Belt-Purcell shows a small range in crustal residence age throughout a 20-km succession, the Dalradian shows an unusually wide variation in crustal residence age. (See also ref. 35.)

exceeds the depositional age by 200–800 Myr, whereas available Sm-Nd analyses of Archaean sediments from Isua, Malene, Pilbara and Fig Tree deposits indicate crustal residence ages approximately coincident with their stratigraphic ages^{4,6,8,28}. This result has been interpreted to indicate that these Archaean sediments are close to first-cycle⁴, because short time intervals around 100 Myr have elapsed between extraction of parent material from the mantle and deposition of the sediment. The contrasting character of the Archaean and Belt-Purcell sediments indicates that the latter has a longer average time interval between crustal formation and sediment deposition and possibly a more extensive history of recycling. The Windermere Supergroup sample (Table 1) has a lower $^{143}\text{Nd}/^{144}\text{Nd}$ ratio (0.51154) than that of the Belt-Purcell samples, and higher crustal residence age of 2.4 Gyr, perhaps reflecting the contribution of a different, older source material or proportion of such material to the Windermere.

The sedimentology of the Belt-Purcell rocks does not constrain their source. However, to evaluate one of several possible source areas, eight Canadian Shield basement samples have

been obtained from cores in southern British Columbia and Alberta recovered from depths of 2,200–3,700 m. The results for these samples (Table 2) are compared with previous Nd isotopic analyses reported from the Canadian Shield⁸. Crustal residence ages for the eastern and western parts of the shield are similar and range respectively over 2.6–3.2 and 2.8–3.4 Gyr, with the one exception of a Grenville composite which has a crustal residence age of 1.5 Gyr. No part of the Canadian Shield has yet been identified which has a 2.0 Gyr crustal residence age such as might have acted as a single eastern sediment source to the Belt–Purcell, and furthermore, no mixture of these Canadian Shield regions west of the Grenville Province yields an average crustal residence age of 2.0 Gyr. If multiple sources with a range of crustal residence ages are involved, they must have become effectively homogeneous by the time of deposition.

The range in crustal residence ages for both modern river particulates²⁹ and Belt–Purcell sediments suggests that the Belt–Purcell material, like modern river sediment, is the product of

effective homogenization accompanying fluvial processes. Lithofacies evidence of braided stream, alluvial fan and deltaic deposits supports this notion, as does the general uniformity of sediment mineralogy and geochemistry^{12,23,26,30}. By analogy with modern major river systems, the Belt–Purcell succession may be the product of erosion across a large drainage area, and sediment sources may not have been restricted to proximal areas.

It should be emphasized that the particularly restricted range of crustal residence age estimates found for the Belt–Purcell is not a feature of all sedimentary successions. For example, the Dalradian Supergroup of Scotland, for which considerable data are available, exhibits very different characteristics (Fig. 2c)^{4,31}. The Dalradian was deposited with an interval extending over 0.70–0.51 Gyr, and shows a very wide range of crustal residence ages (1.7–2.8 Gyr). These results are consistent with localized and heterogeneous source regions, accessed by drainage systems of restricted areal extent. The Dalradian results provide an

excellent example of the value of Sm-Nd isotopic analyses of sediments for limiting the nature of sediment source regions.

A comparison of crustal residence ages for the Proterozoic Belt-Purcell Supergroup and sediments of other depositional ages (Fig. 3) shows that all sediments deposited since 2.0 Gyr have crustal residence ages well in excess of their stratigraphic ages. Assuming that the samples analysed are typical of sediment of their respective stratigraphic ages, it appears that the source areas of sediments deposited before ~2.0 Gyr must include a large component of material with a comparatively short crustal residence time. In contrast, the younger sediments are dominated by recycled continental components with relatively long crustal residence times, and minimal additions of contemporary mantle-derived material. Interestingly, the average crustal residence age for modern river particulates, Palaeozoic sediments and the Belt-Purcell Supergroup are all around 1.7–2.0 Gyr. Although it might be argued that this pattern is an artefact arising from limited sampling and that the Belt-Purcell may be atypical of the global sedimentary mass existing at that time, it seems more likely that the input of new mantle material into the sedimentary mass has been minor over the past 1.5 Gyr or so. Because the evolution of the sedimentary mass is likely to be reasonably representative of at least the upper part of the continental crust, it would appear that the evolution of the continents themselves has also been dominated by recycling.

An important conclusion from the evidence now available is that the mean crustal residence age of clastic sediments, and by inference that of the continental crust during much of the Archaean, differed little from that expected for contemporary additions from the mantle at that time. This observation eliminates the possibility of major contributions from pre-4.0 Gyr continental crust, and suggests that the residence time of light rare-earth enriched material at the Earth's surface was short during this interval^{32,33}. The dominance of material with a short crustal residence age evident in the archaean sedimentary mass is reduced markedly throughout the Proterozoic. Recycling and cannibalism of older continental crust has dominated the Proterozoic and Phanerozoic evolution of the sedimentary mass.

Metamorphism of reduced granulites in low-CO₂ vapour-free environment

William Lamb & J. W. Valley

Department of Geology and Geophysics,
University of Wisconsin, Madison, Wisconsin 53706, USA

Pervasive flooding of CO₂ has been proposed as the cause of granulite facies metamorphism that is capable of producing many distinctive characteristics of the deep continental crust: reduced water activity, orthopyroxene-bearing assemblages, depletion of large-ion lithophile (LIL) elements, and dehydration^{1–6}. The calculations presented here of C–O–H fluid composition for conditions of granulite facies metamorphism show that oxygen fugacity (f_{O_2}) estimates from many terranes are sufficiently low that the addition of CO₂-rich fluid causes graphite to precipitate. For values of pressure (P) and temperature (T) common to granulites, and with f_{O_2} slightly below the quartz–fayalite–magnetite buffer (QFM), the addition of CO₂ sufficient to grow 10 vol. % orthopyroxene requires the precipitation of 1.5 vol. % graphite. As 0.1 vol. % graphite is readily recognizable, but is not reported in most low f_{O_2} granulites, these rocks have not been flooded by CO₂, and low f_{H_2O} is probably due to extraction of a magma or recrystallization of an already dry rock^{7,8}. Granulite terranes may thus result from a combination of these three processes and the dominance of any one cannot now be demonstrated on a regional basis.

Calculations in the C–O–H system show that there are six important fluid species (H₂O, CO₂, CH₄, CO, H₂, O₂) which can be related by four independent equations^{9–11}.

At known P and T there are eight variables in this system, the six fluid species, the fluid pressure (P_F) and the activity of graphite (α_C). If a free-fluid phase is present, a condition required by CO₂ infiltration, then $P_F = P_{Lithostatic}$ (P_L) and equation (5) can be assumed.

$$P_L = P_{H_2O} + P_{CO_2} + P_{CH_4} + P_{CO} + P_{H_2} + P_{O_2} \quad (5)$$

By assuming a free-fluid phase there are now five equations and seven unknowns (as P_F has been fixed) and by fixing the value of two variables it is then possible to calculate the values of the

Fig. 1 *a*, *b*, C-O-H fluid equilibria at 700°C, $P_L = 7$ kbar. Graphite is stable only along the outermost solid curve. Outside this curve $\alpha_C < 1$ at $P_F = 7$ kbar. Inside this curve $P_F < 7$ kbar so that a freely-migrating fluid at lithostatic pressure cannot exist within this region. Isopleths of $\log f_{O_2}$ (dashed) show the effect of an oxygen buffering mineral assemblage (these isopleths are calculated assuming $\alpha_C = 1$ within the graphite stability curve). *b*, An enlargement of the area within the box in *a*, showing the intersection of the $\log f_{O_2} = -17$ isopleth with the graphite stability curve at point A. At this point $X_{CO_2} \approx 0.3$ and addition of CO_2 will precipitate graphite. For these conditions the amount of CO_2 necessary to stabilize 10 vol. % orthopyroxene would precipitate 1.5 vol. % graphite.

five remaining variables. In a graphite-bearing system where $\alpha_C = 1$, it is thus possible to calculate the fugacity of five fluid species by determining the fugacity of one. If graphite is not present the determination of the fugacity of two fluid species allows the determination of the other four as well as α_C .

The calculations summarized here were performed by the program CALCOH which employs a hard-sphere modified Redlich-Kwong equation of state for H_2O , CO_2 and CH_4 (refs 12, 13), and the Gibbs energy of each fluid¹⁴. Calculations of fluid fugacities were made with and without consideration of non-ideal mixing by these three fluid species, with a general agreement of better than 0.1 log unit.

Results of these calculations are shown as a function of $\log f_{CO_2}$ versus $\log f_{H_2O}$ at constant $T = 700^\circ C$, $P_L = 7$ kbar (Fig. 1*a*, *b*). The outermost solid curve delineates the stability field of graphite. Along this curve $\alpha_C = 1$, $P_F = P_L = 7$ kbar, and knowledge of the fugacity of any one of the six fluid species determines the system. Any point inside (below and to the left of) the graphite stability curve is equivalently fixed for a lower P_F as indicated by the 1-, 3- and 5-kbar lines. These pressure contours are calculated assuming $\alpha_C = 1$. It is important to point out that for a graphite-absent rock, where $\alpha_C < 1$, these contours become the upper limit to P_F . Thus, at $P_L = 7$ kbar there will not be a free-fluid phase for values buffered inside of the graphite stability curve as $P_F < P_L$. The dotted curve (Fig. 1*b*) satisfies the relation $P_{H_2O} + P_{CO_2} = 7$ kbar. As high-temperature rocks are ductile with relatively little strength, the region above this curve is geologically inaccessible as a fluid overpressure would result, allowing fluids to escape. The $\log f_{O_2}$ contours are calculated at $P_F = 7$ kbar outside (above) the graphite stability curve at $\alpha_C < 1$, and $P_F < 7$ kbar inside graphite stability at $\alpha_C = 1$. Only

on the graphite stability curve can $P_F = 7$ kbar in the presence of graphite ($\alpha_C = 1$). An important ramification of this diagram is the instability of 7 kbar of fluid inside the graphite stability curve.

The significance of this result is seen for a rock where $\log f_{O_2}$ is buffered to -17 at 700°C, 7 kbar (dashed isopleth in Fig. 1). At low f_{CO_2} (near point C) graphite is unstable at $P_F = 7$ kbar. However, if CO_2 infiltrates the rock it becomes the dominant fluid species at a very low CO_2/R as pore space will be low at these P and T and no other fluid species are assumed to be buffered (CO_2/R is the CO_2 /rock ratio calculated from the moles of oxygen; some workers prefer to use this weight ratio, the conversion being 1.0 atom ratio ≈ 0.5 wt ratio). If infiltrating CO_2 dilutes intergranular H_2O then the system will increase in f_{CO_2} (and α_C) following the $\log f_{O_2} = -17$ isopleth towards the right from point C and intersecting the graphite stability curve at point A at which time graphite becomes stable and $X_{CO_2} \approx 0.3$. The system is then invariant in the presence of graphite. Any additional CO_2 infiltration will be buffered and will drive reaction (1) to the left, precipitating graphite and exhausting the oxygen buffering capacity of the rock. As long as this buffering capacity is maintained CO_2 will be converted quantitatively to graphite and CO_2/R for infiltration can be calculated from the amount of graphite that is precipitated. Such CO_2/R values are considered maxima because some graphite might predate and be unrelated to CO_2 infiltration.

An estimate of the amount of CO_2 -flooding necessary to form a granulite can be made from modal analysis and consideration of reaction progress for dehydration reactions. For example, based on the idealized stoichiometry of the amphibole breakdown reaction:

it is estimated that in certain rocks from the Adirondack Mountains¹⁵ H_2O was buffered at $X_{H_2O} = 0.12$, at 700°C and 7 kbar. If 10 vol. % orthopyroxene formed by reaction (6) in response to CO_2 infiltration then CO_2 must have continuously diluted all evolved H_2O . In this example, H_2O must always comprise 12 mol.% of the fluid ($X_{CO_2} \approx 0.88$), and the total CO_2/R is estimated at 0.1. If conditions of $X_{H_2O} \approx 0.1$ from the Adirondacks^{8,15,16} are similar to those of other granulite terranes then values of $CO_2/R \sim 0.1$ should generally be necessary to form granulites by CO_2 flooding. This value is, however, a conservative estimate and values of $CO_2/R = 0.25$ have been independently estimated². Higher CO_2/R values would cause precipitation of larger amounts of graphite in reduced conditions.

In a rock with < 0.1 vol. % pore space, infiltration equal to $CO_2/R = 0.1$ will precipitate ~ 1.5 vol. % graphite. At low porosity, the amount of graphite precipitated depends only on CO_2/R and is independent of f_{O_2} as long as f_{O_2} is buffered to within the stability of graphite. If a high pore volume of 1% is chosen then the amount of graphite is negligibly reduced to 1.47%. Regardless of its form, as little as 0.1% graphite is easily identified either macroscopically or in thin section allowing reliable identification of rocks that have undergone very small amounts of infiltration ($CO_2/R > 0.007$). Thus it would be difficult to miss evidence for CO_2 infiltration in low f_{O_2} rocks.

The general applicability of these calculations is dependent on what values of f_{O_2} are buffered during granulite facies metamorphism. If f_{O_2} is buffered below reaction (1) then large amounts of readily observable graphite must be present to satisfy models of CO_2 flooding, while if f_{O_2} values exceed the stability of graphite then the absence of graphite provides no information as to CO_2/R .

Unfortunately, the presence of graphite by itself does not necessarily indicate CO_2 infiltration even though it obviously signifies f_{O_2} values less than reaction (1). The problem arises because much graphite of premetamorphic, biogenic origin is preserved in granulites¹⁷, and thus the presence of graphite, which may be 2–10 vol. % in some deposits¹⁸, indicates CO_2 infiltration only if lower grade equivalents are graphite-free. Glassley³ concludes that CO_2 flooding is indicated by the

Fig. 2 Values of f_{O_2} for granulite facies samples estimated from coexisting magnetite + ilmenite. Reaction (1), which closely approximates the maximum f_{O_2} stability of graphite, and QFM²⁶, the quartz + magnetite + fayalite O_2 -buffer, are shown for reference at 7 kbar. Samples: $\circ$, from Scourie²⁵; $\square$, from Quebec²⁴; $\triangle$, from south Quebec²³; +, from the Adirondacks²². Graphite was not reported in most samples indicating that if CO_2 infiltration occurred, amounts of CO_2 were very small, $CO_2/R < 0.007$, and were not sufficient to account for granulite formation.

presence of graphite in two granulite terranes, but this has been criticized on the grounds that graphite-absent amphibolite facies rocks are not correlative with graphite-bearing granulites¹⁹. The great difficulty in correlating across the amphibolite-granulite transition has thus far prevented successful application of this test; however, the presence of small amounts of graphite is still restrictive as it places an upper limit to CO_2 infiltration. For example, it has been estimated that 35% of the rocks in an area of the Marranguit Peninsula, West Greenland contain graphite at levels of $< 0.01\%$ (ref. 20). If all of this graphite was precipitated by CO_2 infiltration then a CO_2/R value of < 0.0007 is indicated, which is not enough to form these granulites. If some graphite is biogenic in origin then CO_2/R would be less, possibly zero.

Coexisting Fe-Ti oxides have been successfully used to estimate f_{O_2} and temperature in a wide range of igneous and high-grade metamorphic terranes²¹. Values from four studies of granulites are shown in Fig. 2 (Adirondacks²², Quebec^{23,24}, and Scourie²⁵). These values are from several rock types including charnockites, anorthosites, metagabbros, granites, trondhjemites and a titaniferous magnetite deposit. Because most f_{O_2} values plot below reaction (1), even when considering an uncertainty of $\log f_{O_2} \pm 0.5$, it is clear that most of these samples should contain graphite if they were infiltrated by CO_2 . No graphite is reported for any of the samples from refs 22, 23 and 25. We have further examined the Adirondack samples²², both in thin section and macroscopically, but have observed no graphite at the 0.01% level.

The assemblage, biotite + K-feldspar + magnetite + ilmenite, buffered f_{O_2} and f_{H_2O} in an Adirondack charnockite. The estimated values are $\log f_{O_2} = -17.2 \pm 0.4$ and $\log f_{H_2O} = 2.65 \pm 0.65$ (ref. 16). These values are plotted in Fig. 1 (point B), showing that if $\alpha_C = 1$ then P_F must have been ~ 4 kbar for this sample (if $\alpha_C < 1$ then P_F was less). Thus, these estimates indicate that no free-fluid phase could have coexisted with this rock at the pressure and temperature estimated for granulite facies metamorphism, unless the metamorphic fluid deviated substantially from the C-O-H system. We consider the presence of such great amounts of other fluid species (such as H_2S , N_2 , Ar, HF, NaCl) to be unlikely on a regional basis. Common orthopyroxene-bearing assemblages in granulites indicate $\log f_{H_2O}$ is significantly below 3.5 ($X_{H_2O} \leq 0.1$), and such low f_{H_2O} is generally ascribed to all granulite terranes based on melting equilibria as well as dehydration reactions. If the rocks in Fig. 2 were buffered at low f_{H_2O} then none of these samples could have been infiltrated by significant CO_2 as a free C-O-H fluid at $P_F = 7$ kbar would

not be stable. It is thus likely that all of these rocks represent fluid-absent granulite facies metamorphism.

Further studies are necessary before it is possible to generalize about the fluid conditions of the lower crust. These results show that some common, granulite facies rocks have not been flooded by sufficient CO_2 to explain their genesis. However, compelling evidence indicates that granulites from certain quarries in southern India were stabilized by infiltrating CO_2 (refs 2, 4, 6). Graphite is not reported in these rocks, but since f_{O_2} is buffered to above QFM by the reaction 3 ferrosilite + $1/2 O_2 =$ magnetite + 3 quartz (R. Newton, personal communication), graphite is not expected regardless of whether CO_2 flooding occurred or not. Thus the results reported here may not be at variance with those from southern India. Extreme gradients in f_{CO_2} and the absence of pervasive fluid movement is reported for some localities in the Adirondacks⁸. If such heterogeneous fluid conditions are representative of granulite facies terranes elsewhere, then low f_{H_2O} values may indicate either extraction of magmas, channelized CO_2 infiltration, or metamorphism of already dry rock, and these processes may operate in close proximity. Very real contrasts in process may also exist from terrane to terrane due to differences in age and/or tectonic style.

This study was supported by grants from the Gas Research Institute (5083-260-0852), the NSF (EAR81-21214 and 83-11772) and the Geological Society of America Penrose Fund (3256-83). We thank P. E. Brown, T. C. Juster, E. J. Essene and W. E. Glassley for helpful conversations and reviews.

Note added in proof: We have used the calibration of Buddington and Lindsley²¹ to estimate f_{O_2} from Fe-Ti oxides rather than that of Spencer and Lindsley²⁷ (1981) (D. H. Lindsley, personal communication). More recently, unpublished experiments of Anderson and Lindsley yield somewhat lower T at low f_{O_2} (D. H. Lindsley, personal communication) and suggest that the oxides from Quebec²⁴ have reset after metamorphism. Most of the other values in Fig. 2 are not significantly affected and thus the conclusions of the study are not changed.

Black acidic snow in the remote Scottish Highlands

T. D. Davies, P. W. Abrahams, M. Tranter,
I. Blackwood, P. Brimblecombe & C. E. Vincent

School of Environmental Sciences, University of East Anglia,
Norwich NR4 7TJ, UK

Parts of Scotland experience large acidic depositions^{1,2} which may result in ecological damage³. Some highland areas appear to suffer enhanced acidic input² which frequently exhibits pronounced episodicity⁴. Acidic snowfall leads to acidic flushes during snow-

pack melting^{5,6}. Polluted grey snow layers have been reported in Scandinavia⁷⁻¹⁰, but we present the first documented case remote from major pollution sources of a distinctive black, acid snowfall episode with pH 3.0. The particulate deposit was very large and consisted of ~29% carbon; the remaining fraction included particles which could be identified as coal fly-ash. The heavily polluted air originated to the south-south east and was probably transported at an altitude of ~1,000–1,500 m in association with a stable atmospheric layer whereupon particles were efficiently scavenged by snow. Such transport and deposition mechanisms may produce the greater pollutant deposition sometimes observed in mountain areas². Similar events may not be rare and could make an important contribution to the annual pollutant input.

Shortly before 06.00 on 20 February 1984 a black snowfall (~5 cm) fell in the Cairngorm mountains (data from Aviemore Meteorological Station). Our survey, by road and foot transects in the more accessible zones, indicated that ~200 km² were affected. Individual samples (22) were collected within hours of falling. Because of the difficult conditions, the sample locations were not equally spaced but were biased towards those that appeared to be close to the eastern and western extremities of the fall. The particulate loading was exceptionally heavy (~0.01 g l⁻¹ of melted snow) and our conservative estimate is a deposit of 0.1 tonne km⁻². Detailed analysis has been undertaken on samples collected at 1,080 m, OS National Grid NJ013046. Our survey of snow packs southwards to Edinburgh, a few weeks later, revealed no trace of the event which by then had evolved into a distinctive grey layer ~40 cm thick in the Cairngorms. Local residents claim that black snow has fallen a number of times annually in recent years and appears to favour higher altitudes.

Figure 1a shows the synoptic pattern. For several days preceding the event, a ridge from a strong anticyclone to the east influenced the eastern side of the United Kingdom. Pronounced anticyclonic subsidence inversions were observed (Fig. 2) and at 00.00 on 20 February 1984 the lapse rate in the sub-inversion air was close to the dry adiabatic value, unlike the previous day when it was relatively stable¹². Snow showers, hail showers and cumulonimbus development were also observed in NE Scotland and off the coast at around 06.00 and during the following daylight hours¹². The lower boundary of the black snow layer was a thin stratum of hailstones.

Back trajectories for air over the Cairngorms are shown in Fig. 1b. The air flowed over a broad corridor of industrial and urban activity from the Trent Valley and southern Yorkshire, northwards over Edinburgh and Dundee. Given the uncertainties of trajectory analysis, the large industrial area of Tyneside-Teesside could have contributed, as could smaller zones of activity. European sources could also have contributed to the overall atmospheric pollutant loading, as black atmospheric

Table 1 Composition of black snow and composition range of 12 other snows collected within 2–3 hours of falling during January–April 1984

	pH	SO ₄ ²⁻	Cl ⁻	NO ₃ ⁻	NH ₄ ⁺	Ca ²⁺	Mg ²⁺	Na ⁺	K ⁺	Charge balance
Black snow	3.0	19.8	14.8	20.9	0.3	0.63	0.52	4.52	0.39	+5.4%
Other snows	3.5–4.7	0.27–4.86	0.15–10.23	0.11–3.52	ND	ND	0.02–0.64	0.07–4.45	ND	ND

Ion concentrations are given in p.p.m.; pH was determined immediately on melting and after filtering through a 0.45-μm Oxoid membrane. Ion determinations were made after storage at 4 °C. Anions were determined on a Dionex Model 12 ion chromatograph (precision ~5%). Cations were measured on a Pye Unicam spectrophotometer (Na⁺, ±0.1; K⁺, Mg²⁺, Ca²⁺, ±0.02) except for NH₄⁺ which was determined by the indophenol blue method on an autoanalyser. There is some evidence that the charge balance is due to organic ions, although pH measurement errors may make a contribution. Charge balance is excess equiv./total equiv. ND, not determined.

particle episodes have been observed in Sweden with winds in the England to Poland sector¹⁹. Pollutant plumes from individual large sources can be tracked for hundreds of kilometres^{20–22} and when they become entrained within or beneath an elevated stable layer there may be little cross-wind dispersion and retention of plume coherence for considerable distances²⁰. The importance of transport above the mixing layer is that the process of dry deposition is inhibited and there is potential for very long range transport²³. Long-range transport of power plant plumes has been found, in the United States, to be favoured at heights of ~800–1,500 m at night when wind speeds were up to ~14 m s⁻¹ at this level; when surface wind speeds were <4 m s⁻¹; when emission was into the lower atmosphere with a dry adiabatic lapse rate and the plume became confined in a more (and becoming more) stable atmosphere²⁴. These atmospheric conditions show strong similarities with those prevailing in this case¹². Such stable plumes have been reported to be dry-deposited on high terrain at night²⁵.

The elevation of the mountains, the geography to the south, black snow distribution and the requirement for little-dispersed, heavily-polluted air to be available for scavenging suggest that advection of the greater proportion of the pollution was within or just below the subsidence inversion layer. This implies that the pollution would have to rise to about 1,000 m and implicates large emitters producing buoyant plumes, although low-level emissions may have made a contribution (synoptic observations of smoke and haze indicated a northward transport of pollution in the lower layers; Fig. 2). Power station plumes, for example, can rise to these heights under the light wind conditions²⁶ which prevailed during the previous night¹¹. Figure 2 shows the heavily polluted air being made available for snow scavenging over the Cairngorms. It was clear that snow scavenging, and not dry deposition, was the removal process as the particles were

Fig. 1 a, Synoptic pattern at 06.00 on 20 February 1984¹¹ with locations referred to in Fig. 2 (L, Lerwick; S, Shanwell; H, Hemsby). b, Back-trajectories from the Cairngorms at 00.00 (●) and 06.00 (—) on 20 February 1984, at 6-hour intervals. The geostrophic approximation for the surface pressure distribution was used. The plan of the 00.00 trajectory agrees well with the observed 850 mbar winds¹² although use of these would increase the length of the 6-hour trajectory by 40%. There are considerable uncertainties and debate over trajectory analysis^{4,13}. The 850 mbar wind has been used¹⁴ and the use of the surface pressure field is considered to be robustly appropriate^{15–18}. In this case the cross-isobar component of flow was restricted to a very shallow layer of air near the ground¹². Both trajectories are sufficiently similar for us to be confident (in the absence of an exact time for the event) of the likely pollutant source regions.

Fig. 2 Schematic cross-section along back-trajectory to the Trent Valley. Shown are dry-bulb temperature soundings at 00.00 on 20 February 1984 (see Fig. 1). Tyneside and Tees-side are industrial areas to the east of the probable trajectory, but may have contributed to the 'regional' pollution plume. Advection in association with the inversion layer made available little-dispersed, heavily-polluted air for scavenging. Pollution in the less stable, sub-inversion layer was more efficiently dispersed and diluted and further depleted by dry deposition, especially in hilly terrain. The strength and position of the inversion fluctuated temporally and spatially¹²; consequently the northward advection of the inversion-layer pollution should not be regarded as increasing in height in the simple fashion portrayed. No showers occurred along the trajectory south of the Scottish mountains¹¹ and so high pollutant concentrations in the mountain air were available for scavenging via down-mixing induced by topographic disturbance, and compensating downdraughts associated with the cumulus circulations. These cumulus circulations may have drawn in volumes of the heavily polluted air, effectively 'concentrating' the pollution to produce a pronounced localized deposition²⁶.

incorporated throughout the whole depth of the fall. Snow is a much more efficient scavenger of aerosols than rainfall^{27,28} and scavenging efficiency increasing with decreasing ice-crystal diameter²⁹. This episode consisted of fine-grained snow.

The black snow had a pH of 3.0 at the main sampling site. The volume-weighted mean annual precipitation in this area of Scotland is around 4.5 (ref. 2), although the pH is lower for our recent snow samples from greater elevations (Table 1). Of particular interest are the relatively large excess of Cl^- and the NO_3^- concentrations in the black snow. HCl is very soluble and so will be relatively easily removed once precipitation occurs. NO_x oxidizes before SO_2 (ref. 30) and snow is relatively efficient at removing NO_3^- (refs 28, 29). The molar ratios of NO_3^- : non-sea salt SO_4^{2-} : non-sea salt Cl^- (1.71:1.00:1.04) may therefore reflect pollution plume ageing, different solubilities and differential scavenging, or different sources.

Fog or cloud droplet deposition may increase acidic input at this altitude³¹, but our observations appear to show a systematic increase of pH with height (Table 2), suggesting that this was not the most important mechanism in this case. Snowflakes at lower elevations had a longer fall-path through polluted air mixed down into the mountains from high level (Fig. 2) or, if the cloud enveloped the mountains, the mechanism may have been early scavenging of ascending polluted air drawn into the cloud.

Figure 3 shows many particles which are typical of pulverized fuel (PF) or coal fly ash^{32,33}. The carbonaceous component, which gave the snowfall its distinctive appearance, comprises much of the particulate volume but it is highly porous (with a specific area of up to 80 times that of non-carbonaceous oil-fired fly ash³⁴). The carbon content of the particulate is $29 \pm 1.5\%$ by weight (Hewlett-Packard 185 B CHN analyser). The carbon content of chimney solids from modern UK oil-fired power stations is $<5\%$ by weight³⁴, but values in excess of 20% have been reported in the United States under some operating conditions^{32,35}. Other coal burners produce larger proportions of carbon residue and would have contributed to the black snow carbonaceous component. For example, the carbon content of domestic coal ash is very high³⁴. The carbonaceous residue particles in PF fly ash are often concentrated in the fraction greater than $45 \mu\text{m}$ in diameter³⁴, and as they are highly porous, they will become relatively enriched at the expense of other, heavier fly ash components which settle out much more rapidly in the long-range transport of the plume. In addition, the large surface area of the carbonaceous particles will lead to further enrichment in the snow scavenging process. The carbonaceous residue may be of particular interest to the acidic deposition issue as it has a large capacity for absorbing acids in the plume. The pH of a soot/water slurry decreases with time whereas that of a non-carbonaceous PF fly ash/water slurry increases³⁴.

Besides glassy spheres and the very porous carbon back-ground, other less easily identifiable particles are seen in Fig. 3 and these may be from a variety of sources. Elemental proportions (Table 3) are similar to those of PF fly ash^{35,36} (and perhaps to other industrial ashes though data are not available) although Ca proportions are relatively low (the Ca fraction is soluble, and there are high concentrations in the meltwater) and Fe is higher than 'typical' but well below the 'common maximum'³⁷. The Pb, Mn and Zn concentrations (respectively $1,530 \pm 11$, $4,960 \pm 94$, $9,830 \pm 108$ p.p.m. after HNO_3 and HClO_4 digestion and atomic absorption spectrophotometry) are higher than those typically observed in PF chimney solids³⁸ (especially Zn) but trace elements, in particular Zn³⁹, are known to be enriched on small particles⁴⁰⁻⁴³ which have much longer atmospheric residence times. The log probability size distribution (Malvern 3600 E-type particle size VA3 analysis after ultrasonic dispersion) for the fraction $<4 \mu\text{m}$ diameter ($\sim 70\%$ of the total number) was similar to distributions determined for PF chimney solids⁴⁰, but shifted towards smaller diameters. Our distribution was deficient in $>4 \mu\text{m}$ particles, presumably as a result of preferential removal in the ageing atmospheric plume (this is not inconsistent with carbonaceous component enrichment in the plume when the weight of carbon as a proportion of different size classes of fly ash from PF power stations is considered³⁴).

In the region of the back trajectory there is a total of $\sim 20,000$ MW of PF power station capacity, the largest plant in

Table 2 Snowfall pH variation with altitude on a hill 18 km to the west of Cairngorm

Altitude (m)	280	295	320	410	500	570
pH	2.95	3.00	3.10	3.15	3.30	3.30

It is possible that this variation reflects an 'edge' effect as this was the most westerly sampling point and altitude increased towards the west.

Table 3 Range of percentage contribution of measured elements to the total weight of all 14 constituent elements in black snow samples

Na	2.2-5.4	Ca	0.6-1.1
Mg	4.0-7.5	Ti	0.5-1.3
Al	18.6-24.0	V	0.0-0.1
Si	30.3-44.3	Cr	tr-0.1
S	1.3-1.8	Fe	18.9-21.4
Cl	0.3-0.4	Ni	0.1-0.15
K	1.9-5.1	Cu	0.05

Values obtained by EDAX bulk analysis⁴⁰ over areas of 20 mm^2 of membrane filters (three analyses). The accuracy of determination for each element is around $\pm 5\%$. tr = trace.

Fig. 3 Scanning electron microscope photograph of particulate material which shows many glassy spheres generally $<5\ \mu\text{m}$ diameter. The spongy, lattice-like background is carbon residue. The large sphere to top left is $\sim 8\ \mu\text{m}$ diameter. The cenosphere (porous particle near bottom) may be tarry, coal exudate but is a typical product of oil-firing (they are relatively infrequent in our samples, ~ 1 in 200).

the Trent Valley and southern Yorkshire. Other large buoyant sources include chemical plant near Teesside and an oil refinery (with its own 100-MW oil-fired power station) to the west of Edinburgh (although our trajectory analysis favours a route to the east of the city). Areal sources in cities may have also been sufficiently buoyant to become entrained in the high-level advection. No information is available on the nature of emissions from the refinery although large quantities of SO_2 , NO_x and organics are released from plant in the United States⁴⁴. The refinery particulate discharge is likely to be small⁴⁴ compared to the 20 tonnes per day suggested for a modern UK 1,800-MW PF power station (generating at full load and assuming an ash capture efficiency of 99.3%)⁵⁴. It is expected that oil ash would contain much higher V and Ni concentrations than our samples (166 ± 50 , 176 ± 10 p.p.m. respectively) and more cenospheres⁴⁵.

Whatever the major source(s) of this large pollutant deposit it is likely that disparate activities have contributed. The exposed faces of the evolved grey snow layer produced a distinctive odour which pervaded the mountainside under calm conditions. It was difficult to characterize the smell and to identify the agents, but some observers have described it as an acetone/phenol-type odour. Petrochemical sources may have contributed. The heavy particulate deposit was the most remarkable feature of this episode. For example, it would require the entire emission for more than two hours from $\sim 20,000$ MW of efficiently-operating PF power stations³⁴.

Such severe acidic episodes could enhance the spring snow pack 'acid flush', both through heavy loading and the 'banding' of acidity in the snowpack (A. R. W. Marsh and A. H. Webb, unpublished CEBG report, 1978). It is of interest to note that the weather pattern was similar to that which produces acidic episodes in Scandinavia⁴⁶, from widespread sources. There is some evidence that the frequency distribution of this type is changing on time scales from years to decades (T. D. Davies and P. M. Kelly, unpublished work) and there may be implications for dry as well as wet deposition in polluted air volumes retaining coherence over long distances and becoming available for transfer to the ground in mountain areas²⁵.

We are grateful for the financial support of the NERC and EEC. We thank Dr A. G. Thomas, Institute of Hydrology, for

assistance with NH_4^+ determinations, and the Central Electricity Generating Board for helpful comment and discussion.

Cell size control of development in *Saccharomyces cerevisiae*

Geoffrey R. Calvert & Ian W. Dawes

Department of Microbiology, University of Edinburgh, Edinburgh EH9 3JG, UK

Diploid cells of the yeast *Saccharomyces cerevisiae* in the G_1 phase of the cell cycle are faced with the alternatives of either continuing vegetative cell division or undergoing the developmental processes of meiosis and subsequent ascospore formation, or adapting to starvation conditions if these apply. The course taken is influenced by the nutritional status of the culture medium¹, the presence of both *MATa* and *MAT α* mating-type alleles², and the need for cells to be in the G_1 phase of the cell cycle³. For those cells that continue cell division, size controls operate in both the budding yeast *S. cerevisiae*^{4,5} and the fission yeast *Schizosaccharomyces pombe*^{6,7}. In *S. cerevisiae* the 'start' event initiating the cell cycle is controlled in some way related to cell size because cells below a critical size fail to initiate cell division⁸. The ability of cells to undergo the developmental process of sporulation is related to cell age, in that cells gain this ability just before the emergence of the first bud⁹ and the process of sporulation after initiation is altered in small cells¹⁰. Here we report that the initiation of sporulation is subject to a size control related to absolute cell volume, which is distinct from control by cell age and also independent of the control operating on the initiation of cell division.

Fig. 1 Relationship between the ability of a yeast population to sporulate and the percentage of cells of volume $>26 \mu\text{m}^3$ before the shift to sporulation medium. Cells of strain S41 grown aerobically in continuous culture at dilution rates between 0.02 h^{-1} and 0.09 h^{-1} were examined microscopically and individual cell volumes measured. Cells were collected from 30 ml samples, washed and resuspended in sporulation medium (20 g l^{-1} potassium acetate). After 48 h incubation at 30°C with shaking, the sporulation frequency of the samples was measured. Further samples were taken after 72 h to check that sporulation was complete. The chemostat medium contained (per l): 10 g galactose, 5 g ammonium sulphate, 1.5 g Difco yeast nitrogen base, 1 g Oxoid yeast extract, 0.1 g arginine, 5.5 g potassium dihydrogen phosphate, 10 g dipotassium hydrogen phosphate and amino acids at 0.1 g, pH 7.2.

Initially, it was noted in strains carrying the *whi1* or *whi2* size control mutation^{11,12} alone or in combination with the *spd1* mutation which derepresses sporulation¹³, that smaller cells in the population did not sporulate whereas the few larger cells present did¹⁴. These preliminary experiments suggested that *whi1* homothallic diploids were unable to sporulate, but did not indicate whether this was a direct effect of the *whi1* mutation, or simply an effect of the smaller cell size. This was tested by growing cells in a presporulation medium containing hydroxyurea, an inhibitor of DNA synthesis which arrests nuclear division without preventing mass growth, and therefore causes cells to become enlarged¹⁵. The results are shown in Table 1: *whi1* cells which were normally unable to sporulate could form large numbers of asci when made larger by preincubation with hydroxyurea. This indicates that the *whi1* mutation was not directly preventing sporulation, but was affecting the process through its property of reducing cell size. These results, while indicating that there may be some size control over initiation of sporulation, are subject to other interpretations as mutants were used.

By growing wild-type yeast at slow growth rates in continuous culture, very small cells can be obtained, and cultures with widely varying average cell sizes can be produced by changing the dilution rate¹⁶. We have studied the dependence of sporulation on cell size by growing populations in chemostat cultures over a wide range of dilution rates. Cultures were grown in media in which sporulation is not initiated but in which mitochondrial functions that are essential for spore formation are derepressed. At each steady state the distribution of cell sizes in the cultures was estimated microscopically and samples of the culture were transferred to sporulation medium to assess the extent to which that population of cells was competent to sporulate. From the results, we estimated the average cell size at which half the maximum sporulation frequency was obtained (that is, 40%); this gave an estimate of the critical volume for initiation of sporulation of $26 \mu\text{m}^3$. Figure 1 illustrates the linear relationship between the extent to which a culture sporulated on resuspension in sporulation medium and the proportion of cells of volume $>26 \mu\text{m}^3$ before the shift to sporulation medium.

Fig. 2 Cells of strain 60x61,

<i>MATα</i>	<i>HO</i>	<i>HMLα</i>	<i>HMRα</i>	<i>ade2-40</i>	<i>his4-239</i>	<i>can1</i>	<i>CYH2</i>	<i>ARG4</i>
<i>MATα</i>	<i>HO</i>	<i>HMLα</i>	<i>HMRα</i>	<i>ade2-119</i>	<i>his4-166</i>	<i>CAN1</i>	<i>cyh2</i>	<i>arg4-1</i>

were grown in the chemostat medium described in Fig. 1 legend. This strain requires histidine for growth but not adenine. On meiotic recombination, however, it yields histidine prototrophs and on chromosome segregation it yields red adenine auxotrophs. Cells were collected from 10 ml of chemostat culture, washed in sporulation medium, and resuspended in the least possible volume. The suspension was loaded onto a gradient of Urografin (density $1.04\text{--}1.08 \text{ g cm}^{-3}$, made up in 2% potassium acetate) in 16.5-ml tubes, and centrifuged for 13 min at 60 g. After centrifugation, the part of the gradient containing the cells was split into nine fractions and the cells from each fraction were collected and resuspended in 3 ml of sporulation medium. Samples of each fraction were diluted appropriately and plated onto minimal medium (1.5 g l^{-1} Difco yeast nitrogen base, 5 g l^{-1} $(\text{NH}_4)_2\text{SO}_4$, 20 g l^{-1} glucose, 20 g l^{-1} agar) and YEPD (10 g l^{-1} yeast extract, 20 g l^{-1} peptone, 20 g l^{-1} glucose, 20 g l^{-1} agar) immediately after resuspension and after 48 h incubation at 30°C . The figure shows the percentage sporulation (●), appearance of histidine prototrophs (▲), and appearance of adenine red auxotrophs (■) in each size fraction.

These data could be interpreted in terms other than the existence of a critical cell size control over initiation of sporulation as: first, they only refer to the production of mature ascospores and therefore cells may be initiating, but not completing sporulation; and second, they only deal with average cell sizes of populations, and not with individual cells. The first of these possibilities was excluded by examining the frequency of intragenic recombination at the *HIS4* locus in populations of sporulating cells of different sizes obtained from a single parent culture by density gradient fractionation. The results (Fig. 2) show that small cells were not undergoing meiotic levels of intragenic recombination at the *HIS4* locus or chromosome segregation. Thus, small cells do not proceed as far as the early sporulation event of intragenic recombination.

The sporulation of individual cells was examined by growing cells of strain 60x61, heterozygous at the *ADE2* locus, in a medium giving a range of cell sizes, resuspending them in sporulation medium, and after 20 h of incubation, dissecting out 250 cells of $<30 \mu\text{m}^3$ volume, and 256 cells of $>40 \mu\text{m}^3$ volume. On subsequent incubation, 110 of the latter were found to form red or sectorial colonies, indicating segregation at the *ADE2* locus, while none of the former showed segregation. We were able to measure cell sizes after 20 h in sporulation medium

Table 1 Hydroxyurea restores the ability of *whi1* mutants to sporulate

	Mean cell volume (μm^3)	% Ascus formation
Wild type	78.2	65.4
Wild type (HU-treated)	ND*	62.3
<i>whi1</i>	22.1	1.6
<i>whi1</i> (HU-treated)	50.4	29.0

Cells of strains S41:	<i>MATa HO HMLa HMRa arg4-1 cyh1</i>
	<i>MATa HO HMLa HMRa arg4-1 cyh1</i>
and 65:	<i>MATa HO HMLa HMRa whi1 met5</i>
	<i>MATa HO HDLa HMRa whi1 met5</i>

were inoculated into YEPAG medium (10 g l⁻¹ yeast extract, 20 g l⁻¹ peptone, 20 g l⁻¹ potassium acetate, 1 g l⁻¹ galactose), and after 2 h incubation, hydroxyurea HU; 50 mM) was added to half the samples and incubation was continued. When the absorbance at 600 nm reached 1.0, the cell size distribution of each culture was measured microscopically, and the cells were transferred to sporulation medium. After 48 h in sporulation medium, the frequency of asci in each culture was measured. ND, not determined.

* Large elongate cells of irregular shape.

as cell size in this strain did not significantly increase during sporulation.

The sporulation of individual cells was also examined by photographing 350 cells before and after sporulation on solid medium. No cells smaller than 25 μm^3 sporulated, and the probability of sporulation increased with increasing size above 25 μm^3 , up to a maximum frequency approaching 100% in cells larger than 130 μm^3 .

The cell size control over sporulation was distinguished from the cell age control by examining the sizes at which cells were able to initiate budding. Small cell fractions (obtained by methods described in Fig. 2 legend) were resuspended in rich growth medium and the sizes of budded cells were measured. The minimum size of budded cells was ~17 μm^3 , and about 8% of budded cells were <26 μm^3 in volume. This indicates that some cells of <26 μm^3 volume were capable of budding, therefore the inability of cells smaller than 26 μm^3 to sporulate was not simply due to their being unbudded daughter cells.

We have used a variety of different methods which give consistent results: yeast cells with a volume less than ~26 μm^3 are unable to sporulate, and this effect is unrelated to size control over budding and cell age control over sporulation. These results have interesting implications for other developmental systems. Size (or critical cell mass) control of cell division seems to operate in higher eukaryotes¹⁷ and similar effects may therefore influence the course of higher cell development.

New evidence that growth in 3T3 cell cultures is a diffusion-limited process

Graham A. Dunn & Grenham W. Ireland

MRC Cell Biophysics Unit, 26-29 Drury Lane,
London WC2B 5RL, UK

When a confluent culture of 3T3 cells is wounded, new growth occurs at the wound margins. This indicates that the suppression of growth in the intact confluent sheet is under local control, a phenomenon known as 'topoinhibition'¹, and it has been suggested that intercellular contact is responsible. An alternative explanation for topoinhibition is possible, however, namely that a soluble factor necessary for growth is locally depleted from the medium by cells so that each cell in a confluent sheet normally receives an insufficient supply and its growth is inhibited²⁻⁵. Here we show that the pattern of release from topoinhibition in a wounded culture can be distorted simply by inducing a gentle laminar flow of medium across the wound. Growth remains suppressed at the upstream margin of the wound despite the reduced level of intercellular contact at wound edges. We conclude that the signal for topoinhibition is carried by the flow as would be predicted if it were the local depletion of growth factor.

Hydrodynamic theory predicts the existence of a thin layer of non-turbulent medium next to the cells in which diffusion is the main mechanism of transport. Any growth factor consumed by the cells would thus become locally depleted in this boundary layer. This explanation of topoinhibition is reinforced by the discovery that forced turbulent stirring of the culture medium using either a miniature pump³ or vigorous shaking of the cultures⁴ increases the growth rate of 3T3 cells. Stirring reduces the thickness of the boundary layer and could, therefore, increase the diffusive flux of growth factor to the cells³⁻⁵; however, this interpretation has been criticized on the grounds that stirring could disrupt intercellular contacts and so the alternative hypothesis of growth control by contact is not eliminated⁶. No effects of fluid shear stress on intercellular contacts have been found although shear stress does affect the migration⁷ and cytoskeleton⁸ but not the growth⁷ of endothelial cells in culture. A further criticism is that increasing the viscosity of the medium does not have the effect of reducing the saturation density of 3T3 cultures that might be expected if growth depended on diffusive flux⁶. Thus, we have developed a direct test of whether the release from topoinhibition at wound margins depends on a diffusible factor.

3T3 cells were grown in Petriperm culture dishes in order to maintain steady conditions of pH and gaseous exchange. Confluent monolayers were wounded by scraping away a narrow strip of cells along a diameter of each dish and the medium was replaced with fresh medium containing ³H-thymidine and varying concentrations of serum. In some cultures, the lids were replaced with the apparatus shown in Fig. 1 and the cultures were all incubated for a further 16 h then prepared for

Fig. 1 Diagrammatic section of the apparatus. The motor (Portescap Ltd, type M915L, ratio 1:2,430), which is powered by a constant voltage source, is attached to a Sterilin lid which provides a better location on the Petriperm dish than a Petriperm lid. The 32-mm diameter glass disk is glued to the stainless steel bush and adjusted along the motor spindle to give a separation of 0.8 mm from the Petriperm membrane.

Fig. 2 Effect of different flow regimes and serum concentrations on the distribution of labelled nuclei at wound edges. Swiss 3T3K cells (obtained from Dr C. O'Neill) were grown in bicarbonate-buffered Dulbecco's modified Eagle's medium (Flow) containing 10% fetal calf serum (Seralab) in a 37°C humidified incubator gassed with 15% CO₂ in air. 3×10^5 cells were seeded in 5 ml of medium in 5 cm-diameter Petriperm dishes (Heraeus). After 60 h the medium in the cultures was replaced and on day 5 the cultures were used for the experiment, by which time they had been confluent for 2 days. Precise parallel-sided diametral wounds, 0.9 mm wide, were made with a stainless steel tool guided by a jig. The medium was replaced with 3 ml of fresh medium containing $1 \mu\text{Ci ml}^{-1}$ ³H-thymidine (Amersham International; specific activity 112 Ci mmol^{-1}). In *b*, *c* and *d* the original Petriperm lids were replaced with Sterilin lids bearing motors and the cultures returned to the incubator for 16 h. The cultures were fixed in ice-cold 5% trichloroacetic acid, rinsed in 95% ethanol and air-dried. Autoradiography was performed by attaching stripping film to the cultures, exposing them for 3 days, then developing and fixing. The grain density over labelled nuclei was so high that individual grains could not be distinguished and labelled nuclei could be identified using digital image analysis. A Zeiss RA microscope equipped with luminar objectives and a video camera was used to input a frame showing part of the wound to a digital image analysis system. The background was subtracted and windows for size, shape and grey level were set to identify labelled nuclei. The scale used for plotting nuclear positions is foreshortened along the axis parallel with the wound, as indicated by the two scale bars.

Fig. 3 *a*, Specimen fixed immediately after wounding and stained with Giemsa to show the original parallel-sided wound in a confluent sheet. *b*, Part of the same specimen as Fig. 2*d* but stained with Giemsa. Arrows show direction of flow; most labelled nuclei can be seen on the downstream edge. The extent of migration over the 16 h experimental period can be seen by comparison with *a*. Scale bar, 100 μm .

autoradiography. Information about the different flow patterns was obtained in separate experiments using suspended latex spheres of 2 μm diameter.

In the cultures with unmodified lids, the medium shows the slow convective stirring that is thought to be commonly present in undisturbed cultures². Enhanced incorporation of ³H-thymidine at the wound edges is very marked in 4% or 6% serum (Fig. 2*a*). Most of the edge enhancement is contributed by cells that have migrated into the original wound area. With 8% or 10% serum, the background labelling of cells over the whole cell sheet becomes so high that the edge effect is not discernible.

In the cultures with modified lids but with the glass disk kept stationary throughout the experiment, convection currents are suppressed beneath the disk and the movement of latex spheres appears to be confined to brownian motion. At 6% serum concentration (Fig. 2*b*), the enhanced labelling of cells at the

wound edges is not so marked as in the unmodified cultures. At higher serum concentrations, background labelling beneath the disk is lower than in the unmodified cultures. The extent of cell migration into the wound area does not appear to be affected by the presence of the disk.

If the disk is rotated at 0.77 r.p.m. throughout the experiment, the latex spheres follow concentric circular streamlines, the flow beneath the disk appearing to be entirely tangential with no radial or vertical component. Extensive flow studies with enclosed rotating disks⁹ confirm that this laminar flow is to be expected with our conditions, the velocity varying linearly across the gap from zero at the Petriperm membrane to ωr at the glass disk (where ω is the angular velocity and r is the radial distance from the axis of rotation). With 6% or 8% serum concentration, we see a clear difference in the number of labelled cells at the upstream and downstream edges of the wound. At 6% serum concentration (Fig. 2*c*), the edge effect is suppressed at the upstream edge and, in most cases, it ceases to be noticeable. With 8% serum (Figs 2*d*, 3*b*), the upstream edge effect is noticeable but is still markedly smaller than the downstream edge effect. This asymmetry in labelling of the two wound edges cannot be accounted for by differences in the extent of cell migration into the wound area: the difference in labelling index (proportion of labelled cells) between sampled areas from the upstream and downstream edges within the confines of the original wound area is highly significant (8% serum, upstream: 76/685; downstream: 215/913, $\chi^2 = 41$, d.f. = 1, $P < 0.001$).

The level of serum needed to stimulate new growth beneath a stationary or rotating glass disk is higher than in the absence of the disk. It is unlikely that the disk affects gaseous exchange to the cells since the cells are grown on gas-permeable membrane. The fact that the glass disk, even when rotating, suppresses the vertical component of flow in the medium, suggests

that this reduced growth rate is compatible with the explanation of increased growth caused by shaking cultures⁴. The alternative contact hypothesis does not readily explain these effects.

In the laminar flow experiments, the difference in growth between the two wound edges shows that the normal growth response to local cell density can become distorted by flow. This difference cannot be attributed to a difference in shear stress as this is the same for both wound edges at any particular distance from the centre of rotation. In any case, the maximum shear stress in our system is only $0.012 \text{ dyne cm}^{-2}$, more than 100 times lower than the stresses reported to affect cells^{7,8}. Furthermore, the extent of cell spreading, migration and loss of contact is similar at the two edges (Fig. 3) and so it is unlikely that the difference in growth is a secondary consequence of flow affecting

these properties. The only difference in local conditions between the two wound edges is that at the upstream edge the medium flows off the cell sheet, whereas at the downstream edge it flows off the cell-free wound area. We conclude that the signal for determining cell growth is carried by the flow so that the growth response at any location is influenced by the cell density extending some way upstream. The most likely candidate for a signal of cell density that can be transferred by flow is the concentration of some soluble factor that is released or absorbed by cells. An explanation consistent with the dependence of growth on serum concentration is that the signal is a serum-derived growth-promoting factor.

We thank Patricia Dopping-Hepenstal for growing 3T3 cells and Richard Adams for computer software.

Immunoglobulin-like nature of the α -chain of a human T-cell antigen/MHC receptor

Charles H. Hannum*, John W. Kappler*,
Ian S. Trowbridge†, Philippa Marrack*
& John H. Freed*

* Division of Basic Immunology, Department of Medicine, National Jewish Hospital and Research Center, 3800 E. Colfax Avenue, Denver, Colorado 80206, USA

† The Salk Institute, La Jolla, California 92112, USA

Although the receptor with which T cells bind specific antigen can, like immunoglobulin, distinguish between antigens which differ only slightly in structure, it is unique in recognizing antigen only in conjunction with one of the self proteins of the major histocompatibility complex (MHC restriction)¹⁻⁴. The receptor was identified and characterized in mouse and man by using monoclonal antibodies to receptor idiotypes⁵⁻⁷, and consists of two disulphide-linked polypeptides, an acidic α -chain and a neutral to slightly basic β -chain^{8,9}. Peptide maps have shown that, like immunoglobulin, both chains vary for receptors of different specificities¹⁰⁻¹². T-cell-derived cDNA clones have recently been identified in mouse and man encoding immunoglobulin-like molecules¹³⁻¹⁵. These were identified as derived from β -chain genes through a partial N-terminal protein sequence of the β -chain isolated from a human T-cell tumour¹⁶. We have now purified the α - and β -chains of the receptor of the human T-cell leukaemia line HPB-MLT, and have determined the amino acid sequence of several tryptic peptides derived from each chain. Our results further confirm that the previously reported cDNA clones encode β -chains. The sequence of the α -chain peptides identify this as another immunoglobulin-like polypeptide chain. Particularly striking was an α -chain peptide with high homology to the conserved portion of the immunoglobulin J segment and T-cell receptor β -chains. Surprisingly, the α -chain peptides show little similarity to the sequence predicted by two overlapping putative murine α -chain cDNA clones¹⁷.

Using a monoclonal antibody to the receptor on the HPB-MLT cell line¹⁰, we purified several nanomoles of receptor trace-labelled with ¹²⁵I. The α - and β -chains of the receptor were separated and purified by two-dimensional non-reduced/reduced SDS-polyacrylamide gel electrophoresis (PAGE) as described in Fig. 1 legend. Both chains were cleaved

with trypsin and the resultant peptides were purified by reverse-phase HPLC (Fig. 2). Two β -chain peptides, designated Y and Z, were sequenced (Fig. 3). Identical sequences are predicted by the human cDNA sequence of Yanagi *et al.*¹³, further confirming this cDNA as encoding a β -chain and increasing our confidence that the other chain we had purified on the basis of its covalent linkage to this β -chain was indeed a *bona fide* α -chain.

Eight α -chain peptides were sequenced (labelled A-H in Fig. 2a); except for a few amino acids and in some cases the terminal lysine or arginine, an unambiguous sequence was obtained for each peptide. These sequences, listed in Fig. 3, represent the first reported for an α -chain. Each of the peptides was compared with all known sequences in the Dayhoff protein data base¹⁸ using the Unitary Matrix and the Mutation Data Matrix comparison programs. Obviously, because the peptides are so short each peptide showed sequence similarities to a different random set of bacterial, viral and eukaryotic proteins, but in no case was a perfect match found. However, most importantly, only homologies to immunoglobulins and other T-cell receptor chains occurred among the peptides.

The most striking similarity was found for peptide 'E', which shows clear homology to both T-cell receptor β -chain and immunoglobulin J segments (Fig. 4). The strongest homology is 75% (6/8) with the $J_{\beta 1-2}$ segment from the β -chain of the human T-cell tumour Molt-3 (refs 13, 19) and with the murine T-cell β -chain $J_{\beta 2-3}$ (ref. 20). Note that these homologies occur towards the C-terminal end of the J segments, within the strongly conserved region. This great similarity to β -chain J segments suggests that peptide E might be a particularly high yield peptide derived from some β -chain contaminating the purified α -chain. This possibility is eliminated by the absence of the peptide in the tryptic digest of HPB-MLT β -chain (Fig. 2). The identification of a J segment in the α -chain not only identifies its immunoglobulin-like nature but also predicts that the α -chain is encoded by separate V, J and C genes, and that immunoglobulin-like V-J rearrangements must occur in T cells to produce a functional α -chain gene. Confirmation of this prediction must await isolation of this gene.

Peptides F, G and H also show some similarity to immunoglobulins and other T-cell receptor sequences. Although these similarities are less striking than that of peptide E, they do strengthen the conclusion that the α -chain is an immunoglobulin-like molecule. Peptide G is worth discussing in some detail. This proline-rich peptide contains an acid-cleavable bond between aspartic acid and proline (Fig. 3). We have identified a single acid cleavage site in the HPB-MLT-derived α -chain roughly in the middle of the molecule (C.H.H., unpublished data). By analogy with immunoglobulin and other T-cell

Fig. 1 Purification of the α - and β -chains of the receptor of HPB-MLT. Lysate was prepared as described previously^{7,8,10} from 5×10^{10} HPB-MLT cells and combined with lysate prepared from 5×10^8 ¹²⁵I-surface labelled HPB-MLT cells. The lysate was incubated overnight with excess Sepharose 4B beads coupled with the anti-receptor monoclonal antibody T40/25. The bound receptor was eluted with 0.05 M diethylamine, pH 11, and immediately neutralized with Tris buffer. A portion of the eluate corresponding to 5×10^8 cell equivalents was boiled in Laemmli sample buffer²⁴ and run in a single lane of a 10% SDS-PAGE slab gel without reduction. The lane was sliced from the gel, soaked briefly in sample buffer containing 5% 2-mercaptoethanol, laid along the top of a second 10% slab gel and electrophoresed again. The gel was stained with Coomassie blue (a) and an autoradiogram of the dried gel prepared (b). The 46,000-molecular weight (46K) α -chain and 38K β -chain are indicated in each panel, with molecular weight standards positioned along the diagonal containing proteins whose molecular weight did not change on reduction. For preparation of α - and β -chain from the rest of the eluate, this analytical method was scaled up. One-fifth of the T40/25 Sepharose eluate was loaded along the entire top of a 10% slab gel and run without reduction, with cytochrome *c* added as carrier to protect the receptor from oxidation. The gel was sliced into thin horizontal strips and those containing receptor (~ 85 K), detected by radioactivity, were soaked briefly in sample buffer containing 5% 2-mercaptoethanol, loaded along the top of a second slab gel, and electrophoresed again including 0.1 mM thioglycollate in the cathodic buffer chamber²⁵. This gel was also cut into thin horizontal slices and those corresponding to the α - and β -chains were identified by radioactivity. Finally, all slices containing either α - or β -chain were combined and pulverized. The proteins were eluted with water, dialysed extensively, reduced again with dithiothreitol, alkylated with 4-vinylpyridine²⁶, concentrated by lyophilization and precipitated with acetonitrile. The overall yield from five purifications was ~ 2 -3 nmol of each chain.

Fig. 2 Preparation of tryptic peptides from α - and β -chain. *a*, The elution pattern of the α -chain peptides. The peptides selected for sequencing are labelled A-H. *b*, The elution pattern of the β -chain peptides. The peptides selected for sequencing are labelled Y and Z. In both panels peptides known to be derived from the autodigestion of trypsin are labelled T.

Methods: Samples containing 1-2 nmol of α -chain and 2-3 nmol of β -chain were resuspended in 0.5 ml of 0.05 M ammonium bicarbonate and treated with 10% (w/w) TPCK-trypsin added as two equal aliquots over a 16-h incubation at 37 °C. The reaction was stopped by lyophilization. The lyophilized pellet was resuspended in 100 μ l of 0.1% trifluoroacetic acid (TFA) in water (solvent A). The insoluble core peptides were removed by centrifugation at 2,000g for 20 min. The soluble peptides were injected on a 4.6×250 mm Altex Ultrasphere-I.P. 5 μ C-18 reverse-phase column. The column was eluted at 1 ml min⁻¹, with an 80-min linear gradient of 0-50% solvent B (0.1% TFA in acetonitrile) in solvent A²⁷. The column effluent was monitored at 214 nm and 0.5-ml fractions collected.

receptor proteins, this would place the peptide towards the N-terminal end of the constant region. Similar proline-rich stretches occur in the beginning of the constant region of T-cell receptor β -chains^{13,15} and in many immunoglobulin light- and heavy-chain constant regions²¹. In immunoglobulins, these occur in the β -pleated sheets involved in the interaction between light and heavy chains²², and it is tempting to propose a similar structure and function in T-cell receptor α - and β -chains.

One of the most surprising results of our study is the relatively slight similarity of the α -chain peptides of the HPB-MLT receptor to the reported sequence of a proposed murine α -chain predicted from the pHDS4/203 cDNA clones isolated from a

cytotoxic T-cell clone¹⁷. Overall, the HPB-MLT peptides are no more similar to this sequence than they are to immunoglobulins or T-cell receptor β -chains. Given the extraordinary homology between mouse and human β -chains, it seems unlikely that the function of the T-cell receptor could tolerate such divergence between mouse and human α -chain sequence. Rather, one must consider the possibility that this murine cDNA sequence does not encode a receptor α -chain, but some other immunoglobulin-like molecule. Although this might seem unlikely, several properties of this protein are inconsistent with the known properties of murine α -chains. Murine α -chains are acidic proteins, with N-linked carbohydrate adding as much as

Fig. 3 Amino acid sequence of the α - and β -tryptic peptides. Fractions from the HPLC, containing individual peptides, were pooled and evaporated to dryness by lyophilization. Sequences were determined on an Applied Biosystems gas-phase sequencer using either the '01' or '02' chemistry with TFA conversion of the thiazolinones to phenylthiohydantoin (PTH). Analysis of the PTH-derivatives produced was carried out on a Waters Novapak C-18 reverse-phase column eluted with a complex gradient of 16% acetonitrile in 40 mM sodium acetate, pH 5.0 (solvent A) and 60% isopropyl alcohol in water (solvent B). PTH-derivatives were monitored at 254 nm. Residues in parentheses indicate uncertain assignments. Open parentheses indicate that no assignment could be made at that position, although when at the end of a peptide the open parentheses indicate either a lysine or arginine.

Fig. 4 Comparison of the sequence of peptide E of the α -chain with that of J segments of other T-cell receptor chains and of immunoglobulins. The sequence of peptide E of the receptor α -chain of HPB-MLT is shown aligned with portions of the J segment of human and mouse β -chains^{13,19,20,28}, the J segment predicted by the pHDS4/203 cDNA clones¹⁷, and consensus J segments for human immunoglobulins²¹. Identical residues are boxed. The standard one-letter amino acid code is used: A, alanine; R, arginine; N, asparagine; D, aspartic acid; C, cysteine; Q, glutamine; E, glutamic acid; G, glycine; H, histidine; I, isoleucine; L, leucine; K, lysine; M, methionine; F, phenylalanine; P, proline; S, serine; T, threonine; W, tryptophan; Y, tyrosine; V, valine.

10,000–15,000 to their molecular weight^{5,8,9,23}. The pHDS4/203 cDNA encodes a basic protein with no sites for N-glycosylation. Furthermore, peptide maps of receptor α -chains have indicated variation between T-cell clones of different specificities^{10–12}. However, the expression of the genes detected by pHDS4/203 seems to involve only one V region and one J segment. Further

experiments will be necessary to resolve these apparent discrepancies.

We thank Craig R. Miles for technical assistance in obtaining the N-terminal amino acid sequences, Jim Leibson, Ella Kushnir and Janice White for other valuable technical help, Dr Ralph Kubo for help in the preparation of the immunosorbent beads and for sharing his protein chemistry experience with us, Dr George Tarr of the University of Michigan for his advice in our early attempts to sequence these proteins, and Kelly Bakke, Ruth Roberts and Edna Squillante for secretarial help. This work was supported by USPHS grants CA-36700 (to J.H.F.) and AI-17134 (to J.W.K. and P.M.) and American Cancer Society grants IM-49 (to J.W.K. and P.M.) and FRA-218 (to J.W.K.).

Cell-surface antigens expressed on L-cells transfected with whole DNA from non-expressing and expressing cells

Charles Hsu, Paula Kavathas & Leonard A. Herzenberg

Department of Genetics, Stanford University, Stanford, California 94305, USA

We have shown previously¹ that transfection of mouse L-cells with DNA from JM, a human T-cell line expressing certain T-cell differentiation antigens, yields stable transfectants expressing one or another of these antigens. The identities of the antigens were confirmed by immunoprecipitation and SDS-polyacrylamide gel electrophoresis. We now report that our procedure—co-transfection² with the chicken thymidine kinase gene (*tk*) and whole cellular DNA, selection with hypoxanthine-aminopterin-thymidine (HAT)³, and staining of the cells with fluorochrome-conjugated monoclonal antibodies and fluorescence-activated cell-sorter (FACS) selection—yields transfectants expressing a variety of cell-surface molecules (19 of 21 investigated), most at a frequency of about one per 10³ Tk⁺ transformants. Of these, 9 of 12 were transferred and expressed as readily using DNA from cells which did not express the cell-surface antigens as from tissues or cells that did express them.

We performed Tk co-transfections with DNA from human placenta, kidney, a renal cell carcinoma derived from the same individual as the kidney, and LCL-721, a human B-lymphoblastoid cell line. None of these tissues expresses serologically detectable Leu-1 or Leu-2, except LCL-721, which expresses Leu-1; in none is Leu-2 messenger RNA detectable by Northern blotting using cloned Leu-2 complementary DNA as probe²⁸. DNA from JM, which expresses these genes, served as a positive control.

Tk⁺ transformants were selected by FACS for expression of Leu-1 or Leu-2. As positive controls, we selected transfectants expressing HLA class I antigens or human transferrin receptor, as these are constitutively expressed in all of the tissues we studied. We recovered Leu-2⁺ transfectants from all of the

Table 2 Murine lymphoid antigens detected on transfected L-cells using monoclonal antibodies

human DNA sources, at a frequency of about one per 10³ Tk⁺ transformants (Table 1). We also recovered, though less frequently, transfectants expressing either Leu-1 (from both antigen-expressing and non-expressing sources) or human transferrin receptor.

In our original work with JM DNA, one of the Leu-2⁺ transfectants expressed very high, but unstable, levels of surface Leu-2. The gene for Leu-2 was highly amplified in this transformant^{4,28}. We have now found that 11 of 20 independent Leu-2⁺ transfectants exhibit similarly high and heterogeneous levels of Leu-2. In 10 of these cases, further rounds of selection for the most brightly staining cells have yielded at least a 4-fold increase in antigen expression, resulting in cells that are now over 20-fold brighter than 'normal', stable Leu-2⁺ transfectants. In some cases, we have confirmed Leu-2 gene amplification by quantitative filter hybridization of RNA⁵ and DNA⁶ to a cloned Leu-2 gene probe²⁸.

To further our study using multiple organ and tissue sources and to determine how many of the antigens for which we had available antibodies could be transferred and expressed, we extended our work to mouse DNA transfections. We studied 11 murine cell-surface antigens. Nine are believed to be monomeric glycoproteins. One, Lyt-2, occurs primarily as a heterodimer⁷. The two chains may be encoded by one gene or

Table 1 Human antigens detected on transfected mouse L-cells using monoclonal antibodies

Antigen	DNA donor

Isolation of transfectants expressing novel cell-surface antigens: L(Tk⁻) cells²² were grown in 100-mm tissue culture dishes (Lux) in Dulbecco's modified Eagle's medium with 10% fetal calf serum. DNA was prepared from various tissues as described previously²³. Briefly, the tissues were pulverized under liquid nitrogen, dissolved in 1% sarkosyl, 50 mM EDTA, 0.2 mg ml⁻¹ proteinase K (Merck), followed by treatment with RNase, extraction with phenol followed by chloroform, and caesium chloride equilibrium gradient centrifugation. The purified DNA was recovered (and sterilized) by ethanol precipitation and dissolved in 10 mM Tris-HCl, 1 mM EDTA. Transfections were carried out using a modification of the protocol of Wigler *et al.*²⁴. In most cases the DNA was sheared before precipitation by one passage through a 23-gauge needle. In all cases, 1 µg of Tk-bearing plasmid (the chicken thymidine kinase gene, cloned into the plasmid pBR322 and propagated in the host *Escherichia coli* GM48 (*dam* *mec*)²⁵ was used with 20 µg of genomic ('carrier') DNA per dish of 10⁶ cells. Transfectants were selected for expression of Tk genes by growth in HAT³. They were then selected for expression of specific antigens by staining with fluoresceinated monoclonal antibodies and FACS sorting, as described elsewhere¹. Initial dishes of transfectants were pooled, if necessary, to form dishes of 1,000–1,500 Tk⁺ clones each. These were then collected, and each dish was divided into aliquots of 10⁶ cells, one aliquot for each reagent to be screened. Staining was done at nominally saturating concentrations of antibody, in sterile 96-well V-bottom culture trays. In the initial round of sorting, cells falling within arbitrary 'gates' representing the positively staining cells were sorted into pots and then regrown for further analysis. In some cases it proved possible to clone positively staining cells directly from the initial culture. In most cases it was necessary to enrich with one or more rounds of 'pot-sorting' for bright cells before it became feasible to clone true positives into individual wells.

W6/32 is an anti-HLA framework monoclonal antibody that is specific for HLA heavy chains even when they are in association with mouse β₂-microglobulin^{20,21}. ND, not determined.

* Amplified phenotype (no. amplified/no. positive).

† No. of dishes yielding positive transfectants/total no. of dishes analysed.

Table 3 Expression of mouse genes in transfected L-cells requires mouse DNA

DNA source	Human Leu-2a	Human NGF receptor	Antigen Rat NGF receptor	Mouse 30-E2	Mouse L3T4a
PC12(rat)	ND	ND	5/8*	0/8	0/8
A875(human)	4/6	1/6	ND	0/6	0/6
Peripheral blood lymphocytes (human)	6/6	ND	ND	0/6	0/6

PC12 is a rat chromocytoma expressing NGF receptor; A875 is a human melanoma expressing NGF receptor but not Leu-2. Transfectant cultures were subjected to at least four rounds of sorting and regrowth before being typed as negative. In previous experiments with 30-E2 and L3T4a, no more than two rounds of FACS selection had ever been required to obtain cultures that were >90% enriched for positive cells, when there were positives present in the starting dishes of transfectants. We note that the results with A875 provide another example of efficient transfer of Leu-2 using DNA from a non-expressing source.

* No. of dishes yielding positive transfectants/total no. of dishes analysed.

by closely linked genes. In the case of H-2, the host cell⁸ or the culture medium serum⁹ can supply β_2 -microglobulin to complement the heavy chains encoded by the donor DNA, and permit surface expression.

We used DNA from BALB/c mice, as they differ at several serologically detectable loci from the mouse strain (C3H) from which L-cells were derived¹⁰. Because all of the antigens tested are present on at least 10% of spleen cells^{11,12}, we used spleen DNA as our positive standard. None of these antigens is known to be expressed on any of the other tissues used. The various DNA sources differed little in yield of transfectants for 8 of the 11 antigens tested (Table 2). For the other three antigens (T200, BLA-1 and 30-Fl, not tabulated), we recovered only one transfectant, preventing meaningful comparisons.

For heuristic purposes, we also used DNA from the L(Tk⁻) line itself. We used only those antibodies with which we had previously most readily detected transfectants. We recovered L-cell transfectants positive for the target antigens as frequently with L-cell DNA as with the other DNAs (Table 2).

It is conceivable that the murine antigens are produced by L-cell genes that are active in rare variants in normal L-cell cultures, or which are activated by the transfection process. We therefore transfected L-cells with human or rat DNA and looked for cells expressing murine antigens. We did not isolate any transfectants expressing the murine antigens tested, although we did obtain transfectants expressing Leu-2 or rat nerve growth factor (NGF) receptor at expected frequencies (Table 3). Furthermore, in the case of Ly-1, Lyt-2 and H-2 antigens, the BALB/c DNA-derived transfectants stain with antibodies specific for the donor allotype, showing directly that they express transferred, and not endogenous, genes.

Two antigens for which we obtained transfectants were Lyt-2 (see Table 2) and 30-Fl (data not shown). In the normal animal, each is associated with another cell-surface determinant (Lyt-2 with Lyt-3 (ref. 11) and 30-Fl with BLA-1 (R. Hardy, unpublished)). None of the Lyt-2⁺ transfectants stain with anti-Lyt-3, nor do they contain the Lyt-3 polypeptide when examined by immunoprecipitation and SDS-polyacrylamide gel electrophoresis. However, the one 30-Fl⁺ transfectant isolated also expresses BLA-1. As co-transfer of two unlinked genes is very unlikely¹³, and in light of their association on normal cells, we propose that 30-Fl and BLA-1 are encoded by one gene or by two very tightly linked genes.

The BLA-2⁺ transfectants expressed extremely high levels of antigen, enabling us to perform an initial characterization of the molecule. We immunoprecipitated a 94,000 molecular weight protein consisting of one polypeptide chain. This molecule has now been identified on various murine B-cell lines known from staining studies to be BLA-2⁺ (R. Hardy and G. Calicchio, unpublished).

We believe this to be the first demonstration that several genes can be stably transferred in active form using DNA from tissue sources not expressing those genes. Further, in the case of most of the genes we analysed, DNA from non-expressing sources

appears to be as efficient in transfection as DNA from expressing tissues.

Other studies¹⁴⁻¹⁶, using cloned genes, show an inverse correlation between the activity of genes in gene transfer and their degree of cytosine base methylation. The means by which the genes in our study were originally turned off may not depend on this type of modification, or they may be insufficiently modified to keep them turned off in L-cells. We have readily recovered Leu-2⁺ transfectants using the highly methylated¹⁷ DNA from human sperm. However, we have not recovered any Leu-2⁺ transfectants using DNA from certain human choriocarcinoma cell lines (S. Alberti, C.H. and L.A.H., in preparation); these are also the only DNA sources we have used which do not express antigens of the major histocompatibility complex. We are now investigating whether there is a special mechanism for turning off genes in these cells.

Enhancer sequences have been shown to be important in the expression of certain cloned genes in transfection systems^{18,19}. These *cis*-acting elements increase transcription rate and accuracy, and seem to act in a highly tissue-specific manner. The stringent tissue-specificity attributed to the expression of certain differentially expressed genes (for example, immunoglobulins) in gene-transfer systems does not seem to hold in L-cells for the genes we have transferred using total cellular DNA.

We thank Dr R. R. Hardy for purifying and fluorescein-conjugating most of the anti-mouse antibodies used in this work, and Drs F. Fitch, J. Unkeless, L. Lanier, P. Jones and E. Shooter for gifts of reagents. This work was supported in part by NIH grants CA-04681, GM-28428 and GM-17367.

Evidence for two distinct *c-src* loci on human chromosomes 1 and 20

Michelle M. Le Beau, Carol A. Westbrook,
Manuel O. Diaz & Janet D. Rowley

Section of Hematology/Oncology, Department of Medicine,
University of Chicago, Chicago, Illinois 60637, USA

A number of proto-oncogenes have recently been localized to the chromosomal segments that are the breakpoints in the specific rearrangements noted in human malignant diseases¹. Moreover, rearranged forms of several proto-oncogenes have been identified in malignant cells; in several instances, the proto-oncogene has undergone an alteration as a result of a nonrandom chromosomal rearrangement²⁻⁴. One proto-oncogene that has yet to be associated with human neoplastic disease is *c-src*, the cellular homologue of the transforming sequence of Rous sarcoma virus (RSV). By somatic cell hybridization, *c-src* has been mapped to chromosome 20, but its precise location was not determined⁵. We have now mapped this gene by using *in situ* hybridization of the cloned human *c-src* probe to human mitotic chromosomes. We report here that the human genome contains two loci with strong homology to the coding regions of this oncogene, at 1p34-p36 and 20q12-q13. It is noteworthy that these chromosomal regions are frequently involved in the structural rearrangements observed in haematological malignant diseases⁶⁻⁸.

In situ hybridization⁹ of a ³H-labelled *c-src* probe containing genomic *c-src* sequences spanning exons 10-12 (plasmid pHu-1-c) resulted in specific labelling of two chromosomal regions, the distal short arm of chromosome 1 and the long arm of chromosome 20. Figure 1 shows the distribution of labelled sites in 100

metaphase cells examined. Of these cells, 40 (40%) were labelled on region 1p3, bands p34-p36, of one or both chromosomes 1; these sites represented 13.5% (68 of 505) of all labelled sites ($P < 0.005$). On chromosome 20, 34 metaphase cells (34%) exhibited label on the mid- to terminal segment of 20q. Fifty labelled sites, or 9.9% of all labelled sites, were noted on 20q12-q13 ($P < 0.005$). The distribution of grains from labelled chromosome 1 ($n = 65$) and labelled chromosome 20 ($n = 51$) indicates significant clustering of grains to bands 1p34-p36 and to bands 20q12-q13 (Fig. 2). A small cluster of grains was observed at band 9q34 ($P < 0.005$, 1.8% of labelled sites), suggesting that cross-hybridization to *c-abl* had occurred¹⁰. When the stringency of hybridization was increased (hybridized slides washed extensively at 42 °C rather than 39 °C), labelling was not observed in this region. However, specific labelling of 1p34-p36 (9.6% of labelled sites) and 20q12-q13 (7.9% of labelled sites) was maintained under more stringent conditions (60 metaphase cells examined). *In situ* hybridization with an 800-base pair *Pvu*II fragment containing *v-src*-specific sequences derived from the Schmidt-Ruppin strain of RSV (plasmid pPvuIIIE)¹¹ confirmed the presence of these two loci (data not shown). Although the signal was much weaker than that observed with the human *c-src* probe, a clustering of grains was again observed on 1p34-p36 and 20q12-q13.

RSV is one of the most highly oncogenic of the known retroviruses. Infection of avian fibroblasts with RSV results in a high degree of malignant transformation; this transforming capability of RSV is mediated by the *v-src* sequences¹². Interestingly, infection of cultured mouse bone marrow with RSV results in increases in stem cell proliferation and in self-renewal, two properties associated with myeloproliferative disorders¹³.

We have now regionally mapped the proto-oncogene *c-src* to two sites in the normal human karyotype by using *in situ* hybridization. The fact that the two loci hybridized to both the

Fig. 1 Sub-localization of the human *c-src* gene to two human chromosomes. Distribution of labelled sites in 100 metaphase cells identified significant clustering of grains on regions p3 and q1 of chromosomes 1 and 20, respectively. Human metaphase cells prepared from phytohaemagglutinin-stimulated peripheral blood lymphocytes were hybridized with the ³H-labelled pHu-1-c plasmid DNA which contained a 1.7-kilobase *c-src*-specific insert, encompassing exons 10, 11 and 12 of the human genomic *src* sequence, cloned in pUC8. Radiolabelled probes were prepared by nick translation of the entire plasmid using all four ³H-labelled dNTP to specific activity 5×10^7 – 1×10^8 d.p.m. per μ g. Metaphase cells were hybridized at 10 or 30 ng probe per μ l for 16 h at 37 °C, exposed to autoradiographic emulsion for 8–15 days, and G-banded with the Wright's staining method as described by Harper⁹. The following modifications of the method of Harper were used. Chromosomal DNA was denatured by immersion of slides in 70% formamide in 0.6 $\times$ SSC (0.09 M NaCl/0.009 M trisodium citrate) at 70 °C, pH 7.0. Radiolabelled probe was hybridized in 50% formamide/2 $\times$ SSCP (0.3 M NaCl/0.03 M trisodium citrate/0.04 M NaPO₄, pH 5.0)/10% dextran sulphate/3 mM Tris–0.3 mM EDTA (pH 7.0). After hybridization, the slides were washed extensively in 50% formamide/1 $\times$ SSC, 39 °C, pH 7.0, followed by washes in 2 $\times$ SSC and by ethanol dehydration. For improved chromosome banding, autoradiographs were destained with 95% ethanol-HCl (0.25%, 10 M HCl) and restained, either once or twice.

Fig. 2 Distribution of labelled sites on 65 and 51 labelled chromosomes 1 and 20, respectively. Of 86 total sites on chromosome 1, 68 (79%) were located on 1p34-pter. Of 59 labelled sites on chromosome 20, 50 (84.7%) were noted on q12-qter.

v-src and *c-src* probes suggests that the homology lies within the coding regions of the genes rather than in the intervening sequences that are absent in the *v-src* probe. With man-mouse somatic cell hybrids, sequences homologous to *v-src* had previously been mapped to chromosome 20⁵ and, recently, to its long arm (A. Y. Sakaguchi, personal communication). Southern blot analysis of less strongly hybridizing bands that did not segregate with chromosome 20⁵, suggested that additional loci may exist. Moreover, two related DNA clones corresponding to two separate *src* genes have been isolated from a human genomic library (R. Parker, G. Mardin, R. Lebo, H. Varmus and J. M. Bishop, in preparation), and were assigned to chromosomes 1 and 20 by hybridization of specific probes to dot blots of human chromosomes isolated by fluorescence activated sorting. Whether both of these genes are transcribed is not known; however, human cells contain two related, but distinct, protein forms of pp60^{c-src} (ref. 14).

Translocations involving bands p34-p36 of chromosome 1 have been noted frequently in haematological neoplasia and in solid tumours^{7,8}. We have observed rearrangements involving these bands in 5% of patients with acute non-lymphocytic leukaemia or a myelodysplastic syndrome, and in 10% of patients with non-Hodgkin's lymphoma (E. Brown, J.D.R. and M. M. Le B., unpublished results). Nonrandom deletions of 1p with a breakpoint between 1p13 and 1p36 have been identified in neuroblastomas¹⁵ and in malignant melanomas¹⁶. Abnormalities of chromosome 20 have been observed in a number of patients with haematological malignant diseases. Although loss of one chromosome 20 and translocations involving 20q have been reported, a more common abnormality is a deletion of the long arm of the chromosome. Such a deletion has been noted in patients with acute non-lymphocytic leukaemia or myelodysplastic syndrome, as well as in those with polycythaemia vera^{6-8,17,18}. This abnormality has been described as a terminal deletion involving band q11 (ref. 18). However, at the light

microscopy level, we cannot exclude the possibility that the deletion is actually an interstitial one with breakpoints at q11 and q13. *In situ* hybridization of *c-src* to malignant cells with a del(20q) would provide a definitive answer. We are now investigating these possibilities, along with an analysis of cells with rearrangements of chromosome 1. In view of our findings that *src*-specific sequences are localized to two human chromosomes that are frequently involved in rearrangements, a role for *c-src* in the pathogenesis of human neoplastic diseases should be considered. In this regard *c-src*-related sequences have been found to be expressed in malignant cells of two patients with haematopoietic neoplasms¹⁹.

We thank J. Michael Bishop for the gift of the cloned *src* probes and for valuable discussion, Diane Roulston for technical assistance, and Nanci Carrothers for help in the preparation of the manuscript. Biological properties of human *c-Ha-ras1* genes mutated at codon 12

Peter H. Seeburg, Wendy W. Colby,
Daniel J. Capon, David V. Goeddel
& Arthur D. Levinson

Department of Molecular Biology, Genentech, Inc.,

California 94080, USA

Vertebrate genomes contain proto-oncogenes whose enhanced expression or alteration by mutation seems to be involved in the development of naturally occurring tumours^{1,2}. These activated genes, usually assayed by their ability to induce the malignant transformation of NIH 3T3 cells, are frequently related to the *ras* oncogene³⁻¹⁰ of Harvey (*Ha-ras*)¹¹ or Kirsten (*Ki-ras*)¹² murine sarcoma viruses, or a third member of this family (*N-ras*)¹³⁻¹⁵. Activation involves point mutation which often affect codon 12 (refs 16-26) of the encoded 21,000-molecular weight polypeptide (p21). To provide insight into structural requirements involved in p21 activation, we have now constructed 20 mutant *c-Ha-ras1* genes by *in vitro* mutagenesis, each encoding a different amino acid at codon 12. Analysis of rat fibroblasts transfected with these altered genes demonstrates that all amino acids except glycine

(which is encoded by normal cellular *ras* genes) and proline at position 12 activate p21, suggesting a requirement for an α -helical structure in this region of the polypeptide. The morphological phenotype of cells transformed by the activated genes can, however, depend on the particular amino acid at this position.

The human c-Ha-*ras*1 gene is contained on a genomic 4.7-kilobase (kb) *Bam*HI-*Sph*I DNA fragment¹⁷ and its coding region is distributed across four exons¹⁹. To generate codon 12 mutants, a DNA fragment encompassing exon 1 was cloned into bacteriophage M13 vector mp10 (ref. 27) and exhaustive mutagenesis at codon 12 was performed using techniques similar to those described by Zoller and Smith²⁸. The oligodeoxynucleotides for introducing the desired mutations were synthesized²⁹ in three pools, each pool containing oligomers designed to alter the sequence of codon 12 by one, two or three nucleotides, respectively (Fig. 1). The few mutants not identified in this manner were obtained by repeating the mutagenesis and screening with individually synthesized oligomers.

All mutations so generated were inserted by *in vitro* recombination back into the c-Ha-*ras*1 gene (Fig. 2). This strategy was used to minimize the possibility of obtaining transformed cell clones due to the significant overexpression of otherwise non-transforming genes which can occur when strong, heterologous promoters are used³⁰. To assess the transformation potential of the 20 c-Ha-*ras*1 plasmids, each was individually transfected onto contact-inhibited Rat-1 cells³¹ by calcium phosphate-mediated DNA transfection in the presence of the Tn5-encoded phosphotransferase (*neo*) gene^{32,33}; cells incorporating the exogenous DNA were selected in the presence of the antibiotic G418 (refs 32, 33). Cotransfected markers usually become incorporated together into recipient cells^{34,35} such that individual G418-resistant colonies could be examined for the expression of the Ha-*ras* genes independently of the morphological phenotype of the cells. In this manner we could directly confirm that cells co-transfected with non-transforming c-Ha-*ras*1 genes indeed expressed the encoded polypeptide.

When co-transfected with most of the mutant *ras* genes, 80–90% of the G418-resistant colonies contained cells which

Fig. 1 Mutagenesis of c-Ha-*ras*1 codon 12. The first 18 codons of the proto-oncogene are shown, as carried on the recombinant M13 phage mp10/*ras*-Gly 12. For mutagenesis, three oligomer pools of the sequence 5'-CTTGCCACACCCNNNGGCGCCCA-CCACC-3' were synthesized by a phosphotriester approach²⁹. The actual nucleotides occupying the NNN positions of the three pools are shown; these were designed to alter the codon 12 sequence by one, two or three nucleotides, respectively. To reduce the complexity of pool 2, the oligomer changing glycine to tryptophan was included in pool 3 (see asterisk).

Methods: Oligomers (in pools or individually) were phosphorylated using rATP and polynucleotide kinase, and annealed to single-stranded mp10/*ras*-Gly DNA. Annealings (10 μ l; 10 mM Tris-HCl pH 7.5, 7 mM MgCl₂, 0.1 mM EDTA, 50 mM NaCl) containing 0.1 pmol of template DNA and 0.1 pmol of phosphorylated oligomer were incubated for 5 min at 55 °C. *In vitro* DNA synthesis was initiated by adding 40 μ l of 50 mM Tris-HCl pH 7.5, 7 mM MgCl₂, 0.1 mM EDTA, 1 mM ATP, 100 μ M each of dATP, dGTP, dTTP and dCTP, 5 U *E. coli* DNA polymerase I, large fragment (Boehringer Mannheim) and 400 U T4 DNA ligase (New England Biolabs). After incubation for 3 h at 37 °C, reaction mixtures were extracted with phenol, DNA was precipitated with EtOH, and 2–4% of the DNA was used to transform *E. coli* strain JM103 made competent for DNA uptake. Transformation mixtures (300 μ l) were spread onto bacterial plates (150 mm), yielding several hundred phage plaques. To screen for mutants, these plates were probed by *in situ* hybridization on duplicate nitrocellulose filter-lifts⁴⁵. One set of filters was probed with the oligonucleotide 5'-CTTGCCACACCCGCGGCCAC-3', fully complementary to the original sequence (coding for glycine) and other with a mutant-specific oligonucleotide or oligomer pool. Oligonucleotides were phosphorylated to a specific activity of $\sim 10^7$ d.p.m. per pmol with [γ -³²P]ATP (ICN, crude >4,000 Ci mmol⁻¹) and polynucleotide kinase (NEN). Hybridization was overnight using 10⁷ c.p.m. per filter. To screen for the original sequence, annealings were in 5 $\times$ SSC, 45% formamide, 50 °C and excess radioactivity was washed off in 2 $\times$ SSC, 0.1% SDS at room temperature, followed by 15 min at 50 °C. Conditions for detecting mutants were as follows. For mutants derived from pool 1, a set of 13-mers was used as a probe (5'-NNNGGCGCCCA-3', with NNN represented by GGC, GTC, GCG and GCT). This oligomer mixture was hybridized at 20 °C in 5 $\times$ SSC, 30% formamide, and filters were washed in 2 $\times$ SSC, 0.1% SDS at the same temperature. To probe for mutants derived from pools 2 and 3, oligomer mixtures from these pools were hybridized in 5 $\times$ SSC, 40% formamide at 60 °C and filters were washed in 2 $\times$ SSC, 0.1% SDS at 20 °C followed by a 30-min incubation at 30 °C. All filters were blotted dry after the last wash and exposed to X-ray film for several hours at -70 °C using an intensifying screen. For those mutants not obtained by using pools 1, 2 and 3 (see underlined codons), the following oligomers were synthesized individually and served as mutagenesis primers as well as mutant-specific probes:

5'-CTTGCCACACACGCGGCCCA-3' (Ala)
GGG (Pro)
GTG (His)
GGT (Thr)
CTG (Gln)

To probe for mutants, hybridization was in 5 $\times$ SSC at 20 °C and filters were washed in 5 $\times$ SSC at 20 °C, incubated in 3 M trimethylammonium chloride at 55 °C (W. Wood, unpublished) and briefly rinsed in 2 $\times$ SSC at 20 °C. Phage identified by hybridization as carrying an altered 12th codon were grown in small cultures (2 ml), and DNA was isolated and characterized by dideoxy sequencing^{46–48}.

Table 1 Transformation properties of *ras* mutants

Position 12 codon	Activated genes	Focus formation	Agar growth

Asn		++	+
Gln		+	+

Focus formation was determined by the ability of *ras*-cotransfected Rat-1 cells to form foci (see Fig. 3 legend). Agar growth was assessed by plating individual *ras*-cotransfected subclones, or cotransfected mass cultures, into soft agar⁵¹ at two densities (4×10^3 and 2×10^4 per 60 mm dish) and scoring colonies of >30 cells after 2–3 weeks.

Fig. 2 Construction of *c-Ha-ras1* genes substituted at codon 12. Plasmid *pPBLΔSph*, a derivative of *pPBL116-4* (ref. 19) lacking the 1.7-kb *SphI*-*BamHI* region (containing repeated elements)¹⁹ of the 6.5-kb *BamHI* fragment, was cleaved with endonucleases *XhoI* and *XbaI*. The larger fragment (6.7 kb) containing sequences of the bacterial plasmid pBR322 and *ras* exons 2, 3 and 4, together with the presumed transcriptional terminator of the *c-Ha-ras1* gene, was isolated from a 6% polyacrylamide gel. The 1,086-bp *XhoI*-*BstEII* fragment containing the prelude region of *c-Ha-ras1* (ref. 19) was similarly isolated. DNA carrying the first exon of *c-Ha-ras1* mutated in codon 12 was obtained by gel isolation of a 600-bp *BstEII*-*XbaI* fragment cleaved from *in vitro* synthesized DNA after priming with the 17-mer LAC primer⁴⁶ on the *mp10/ras* mutant phage DNAs. The *BstEII*-*XbaI* fragment with the valine codon was isolated from plasmid pT24-10 (ref. 19). A three-component ligation with these DNA fragments yielded the mutant variants of plasmid *pPBLΔSph* used for transfections. To ensure that each mutant plasmid carried the correction codon substitution, plasmids were screened for the absence of a *NaeI* restriction site spanning codon 12 (refs 16, 17), and a 400-bp *PstI* fragment containing exon 1 was isolated from each plasmid DNA and analysed by DNA sequencing.

were not contact-inhibited, unlike control cells which received only the *neo*-resistance plasmid (see Table 1). The morphological phenotype induced by these activated *ras* genes was reproducibly dependent upon the particular mutation involved. Mutations which gave rise to gene products with the most potent transforming ability (measured by colony morphology) were those encoding valine, leucine, isoleucine, arginine and threonine at position 12. Cells expressing such gene products typically displayed a fully transformed morphology: the cells were consistently round and refractile, and they grew to the highest saturation densities. An intermediate class of mutants (serine, methionine, cysteine, tyrosine, phenylalanine, tryptophan, histidine, aspartate, glutamate, alanine and asparagine at position 12) generated transformants that overgrew the monolayer, although the cells displayed a less striking change in morphology. Mutants with the most subtle transforming activity (lysine and glutamine at position 12) induced foci only after extended times (typically 2-3 weeks). Such cells exhibited a nearly normal morphology. We failed to observe any focus formation in cells co-transfected with *ras* genes encoding either glycine or proline at position 12 throughout five separate experiments, each performed in duplicate. Figure 3 shows representative morphologies of G418-resistant Rat-1 cells co-transfected with these four classes of mutants.

To provide an additional measure of the transformed phenotype, we determined whether cultures co-transfected with each mutant *ras* vector could grow in an anchorage-independent

Fig. 3 Phase-contrast photomicrographs of Rat-1 cells ($\times 40$). Cells were transfected by *c-Ha-ras1* genes encoding substitutions at codon 12 of: a, valine; b, isoleucine; c, tyrosine; d, lysine; e, proline; f, untransfected Rat-1 cells.

Methods: Transfections were performed by a modification of the calcium phosphate precipitation method⁴⁹ on 1.0×10^6 Rat-1 cells using 5 μ g of each of the *c-Ha-ras1*-containing plasmids and 500 ng of pSVNeoBal6, a plasmid containing the neomycin-resistance^{32,33} gene isolated from Tn5 (ref. 33) under transcriptional control of the simian virus 40 early promoter (a 348-bp *PvuII*-*HindIII* fragment⁵⁰). After 48 h, the transfected cells were split 1:3 into selective medium containing Dulbecco's modified Eagle's medium with 10% fetal bovine serum (Hyclone) and 400 μ g ml⁻¹ G418. After 14 days, resistant colonies were cloned using cloning cylinders, or alternatively on occasion passed *en masse*. Monolayers derived from individual clones or mass cultures were scored for morphology and photographs taken 8-16 days after the cells reached confluency. Foci which overgrew the monolayers were scored for their morphological phenotype (indicated by + to +++ on Table 1) as described in the text.

fashion. We found that all G418-resistant cell lines capable of forming foci on monolayers grew in soft agar (Table 1) with plating efficiencies of 0.2-6.0% (data not shown). Colonies co-transfected with Gly 12 and Pro 12 versions of *c-Ha-ras1* genes were unable to grow in agar, even when mass cultures derived from many (10-30) G418-resistant colonies were plated. Despite the additional selection for anchorage-independent growth following G418 selection, cells which were originally flat (those expressing Lys 12 or Gln 12 versions of p21) did not display any obvious morphological changes when replated following passage through agar (data not shown).

These results indicate that the presence of either a glycine or proline residue at position 12 of p21 results in a polypeptide incapable of inducing the morphological transformation of Rat-1 cells, at least when expressed under the transcriptional control of its own promoter. To verify that these vectors indeed directed the synthesis of p21, as well as to determine the relative levels of expression of p21, cloned cells from cultures co-transfected with representative mutant *ras* genes were examined for the expression of the *c-Ha-ras1* p21 gene product. Cellular proteins were labelled with ³⁵S-methionine and extracts were immunoprecipitated with rabbit immune sera raised against the *c-Ha-ras1* gene product expressed in *Escherichia coli*³⁶. The immunoprecipitates were resolved by SDS-polyacrylamide gel electrophoresis and visualized by fluorography. Figure 4a illustrates that anti-p21 antiserum detects the *c-Ha-ras1* gene product in G418-resistant colonies co-selected with active transforming

Fig. 4 Expression of p21 in transfected cell lines. **A**, ^{35}S -methionine-labelled cell lines were immunoprecipitated with rabbit anti-p21 serum (lanes b-i) or with preimmune serum (lane a). Cells were transfected by c-Ha-ras1 genes substituted at position 12 by: lanes a, b, valine; lane c, isoleucine; lane d, threonine; lane e, tyrosine; lane f, phenylalanine; lane g, arginine; lane h, lysine; lane i, untransfected Rat-1 cells. **B**, lysates were immunoprecipitated by anti-p21 rabbit serum (lanes b, d, f) or with preimmune rabbit serum (lanes a, c, e). Lanes a, b, untransfected Rat-1 cells; lanes c, d, cells were transfected by pPBLASph (glycine); lanes e, f, cells were transfected by the Pro 12 mutant.

Methods: Cultures were labelled with $150\ \mu\text{Ci}\ ^{35}\text{S}$ -methionine (Amersham) per ml methionine-free media for 3 h. Cells were lysed in buffer containing 10 mM Tris-HCl (pH 8.0), 50 mM NaCl, 0.5% sodium deoxycholate, 0.5% Nonidet P-40, 0.1% SDS, and 0.5% Aprotinin (Sigma). Lysates were preincubated with formaldehyde-fixed *Staphylococcus aureus* (Pansorbin, Calbiochem) for 30 min, and the bacteria were removed by centrifugation. The supernatants were immunoprecipitated with the anti-p21 polyclonal rabbit serum³⁶ or preimmune serum for 1 h at 4°C. Immune complexes were precipitated by *S. aureus* and the bacteria were washed three times with the lysis buffer. Immunoprecipitated proteins were analysed by electrophoresis on 15% or 12.5% SDS-polyacrylamide gels⁵² and visualized by fluorography after treatment with Enhance (NEN).

genes. Notably, each *ras* polypeptide exhibits a slightly different electrophoretic mobility, extending previous descriptions of p21 polypeptides which display altered electrophoretic mobilities as a consequence of single amino acid substitutions³⁷⁻³⁹. Human c-Ha-ras1 p21 was also detected in cell lines co-transfected with those c-Ha-ras1 genes unable to effect the morphological transformation of Rat-1 cells (Gly 12 and Pro 12) (Fig. 4b). In these cases, the p21(Gly 12) and p21(Pro 12) exhibit indistinguishable electrophoretic mobilities, as found for these polypeptides directly expressed in *E. coli* (W.W.C., unpublished results). These results verify that the failure of these two genes to transform Rat-1 cells was not due to unanticipated mutations preventing the expression of p21.

The observation that p21 *ras* can induce a panoply of morphological phenotypes in Rat-1 cells depending on the amino acid at position 12 is unexpected. Interestingly, certain replacements which engender p21 with a more restricted transformation potential *in vitro* (for example, Lys 12 and Ser 12) appear in retroviral cognates of transduced *ras* genes (v-bas (ref. 17) and v-Ki-ras (ref. 12) respectively). We suspect this underscores the contribution of quantitative effects as well as qualitative changes in p21 on transformation potential. Consistent with this, we have found that sequences extending 1.7 kb 3' of the *Sph*I site in the c-Ha-ras1 gene (containing the reiterated copies of a 28 base pair (bp) element¹⁹) facilitate the expression of p21; when the expression of p21 (Lys 12) is augmented about fivefold in this manner, a more fully transformed phenotype is induced (W.W.C., unpublished results). These findings, together with the observation that extreme overexpression of even normal *ras* genes can induce the morphological transformation of NIH 3T3

cells³⁰, imply that a threshold level of expression exists for each position 12 *ras* mutant, above which any may transform such cells, although this remains to be established for p21(Pro 12).

Computer analysis of the secondary structure of p21 led to the suggestion that the amino-terminal domain of the polypeptide consists of two helical segments separated by a coil region surrounding amino acid 12 (ref. 22). It was predicted that, as substitution of any other amino acid for glycine at position 12 would probably extend the flanking helical regions²², any mutation affecting the coding properties of codon 12 would activate the oncogenic potential of p21 (refs 22, 40). We have tested this prediction and confirmed that while most amino acid substitutions can activate the polypeptide, those least compatible with an α -helical structure (glycine and proline⁴¹) encode polypeptides incapable of morphologically transforming Rat-1 cells, at least when expressed under the control of the normal *ras* promoter. We note, however, that beyond the marked tendency of glycine and proline residues to break α -helical regions within proteins, residues with the highest reported helical potential⁴¹ do not correlate in any obvious way with those at position 12 of p21 which induce the most pronounced changes in cellular morphology. Note that even some amino acids with strong transforming potential (isoleucine, threonine, leucine) have yet to be identified as activating lesions in tumours. Although it is possible that this reflects an inability of some of the 'activated' genes to participate in the oncogenic pathway by which *ras* genes exert their *in vivo* influence, it is most easily explained by the fact that such changes require the substitution of at least two of the three nucleotides which comprise codon 12, whereas all activated genes characterized to date vary from the cellular proto-oncogene by a single nucleotide. If indeed all but two amino acids at position 12 can activate p21 by *in vivo* criteria, it is possible that those with a potentially limited *in vitro* transforming capability escape easy detection when assayed by usual transfection methods; if this is so, the frequency of activated *ras* genes detected to date in tumours may in fact be an underestimate.

The functional alterations directly responsible for the oncogenic activation of human *ras* proteins are unclear. Attempts to discern differences between normal and activated *ras* polypeptides with regard to specificity or extent of nucleotide binding^{36,42,43}, acylation, or subcellular localization⁴⁴ have been unsuccessful. The observation that p21 possesses an inherent GTPase activity which is selectively impaired by an activating Val 12 mutation³⁶ raises the possibility that an inability to hydrolyse GTP may constitutively activate the polypeptide. The availability of *ras* mutants such as those described here and elsewhere³⁹ which encode polypeptides of varying transformation potentials should facilitate further efforts to define the biochemical changes critical for oncogenic activation of p21.

We thank Dr Charles Benton for the preparation of anti-p21 antisera and Joel Hayflick for assistance with the mutagenesis.

Growth-rate dependent regulation of mRNA stability in *Escherichia coli*

G. Nilsson*, J. G. Belasco†, S. N. Cohen† & A. von Gabain*

The rate of production of bacterial gene products is known to vary with the rate of cell growth, the concentrations of many cellular proteins are altered during times of decreased growth rate¹. In addition, proteins whose *in vivo* levels show no significant alterations with changes in cell doubling time must be synthesized at rates that vary in direct proportion to the growth rate of the cell. In certain instances, growth-rate dependent gene regulation has been shown to occur at the transcriptional or translational level^{2,3}. Another potentially important element in the regulation of gene expression is the stability of messenger RNA. We report here the effect of bacterial growth rate on the half lives of four different monocistronic *Escherichia coli* mRNA species. The stabilities of two of these species, the transcripts of the *ompA* and *cat* genes⁴⁻⁶, exhibit a marked dependence on cell growth rate, whereas the half lives of the transcripts of the *lpp* and *bla* genes^{7,8} are constant over a broad range of cell doubling times. Our results indicate that *E. coli* can alter the rate of synthesis of certain proteins by modulating mRNA stability in response to changes in the rate of cell growth.

The *ompA* gene of *E. coli*, which encodes a highly abundant outer membrane protein, specifies an mRNA transcript that has an unusually long half life^{4,5,9}. Previously, it has been shown that the amount of OmpA protein in the outer membrane remains constant throughout a wide range of bacterial doubling times¹⁰. Such invariability requires a mechanism for adjusting the rate of biosynthesis of this protein in direct proportion to the rate of cell growth. To determine whether this bioregulatory mechanism involves changes in the stability of the *ompA* transcript, we studied the decay of *ompA* mRNA in bacteria growing in conditions that yield a range of doubling times.

E. coli strain C600 was cultured at 30 °C in one of three bacterial growth media: L-broth, MOPS/glucose or MOPS/ace-

Table 1 Half lives of individual *E. coli* transcripts at different growth rates

Transcript half lives in bacteria grown in various media				
	mRNA segment length (nucleotides)	L-broth (40 min)	MOPS/glucose (100 min)	MOPS/acetate (200 min)
<i>bla</i>	587	3.3 ± 0.4	3.2 ± 1.0	2.4 ± 0.7
	267	3.1 ± 0.1	3.2 ± 0.5	3.1 ± 0.3
	80	2.8 ± 0.9	2.5 ± 0.5	2.5 ± 0.1
<i>cat</i>		2.3 ± 0.6	—	0.4*
<i>lpp</i>		20 ± 1	—	23 ± 3
<i>ompA</i>	598	13 ± 3	6.8 ± 0.8	4.4 ± 0.6
	340	15 ± 2	5.0 ± 0.3	4.4 ± 0.4
	200	25 ± 2	10.6 ± 2.7	3.4 ± 0.6
	85	21 ± 4	5.9 ± 0.4	3.8 ± 1.0

Half lives are reported in minutes. Messenger RNA segment boundaries for the *ompA* and *bla* transcripts are as previously defined⁹. The cleavage of a single phosphodiester linkage within a segment of a transcript is scored as the degradation of that segment. All experiments were performed with *E. coli* strain C600 growing exponentially at 30 °C. **Methods:** Decay data for the *ompA* and *cat* transcripts were obtained as described in Figs 1 and 2. For the analysis of *ompA* mRNA decay in cells multiplying with a doubling time of 100 min, RNA was extracted from *E. coli* growing in MOPS/glucose¹ 0, 4, 8 and 16 min after rifampicin addition. The decay of the *lpp* transcript in bacteria growing in L-broth and MOPS/acetate was examined by RNA blotting⁹. The RNA samples were collected 0, 20, 40 and 60 min after rifampicin addition, fractionated by gel electrophoresis, blotted onto diazophenylthioether paper¹⁶, and probed with nick-translated plasmid pKEN113, which contains a copy of the *E. coli lpp* gene¹⁷. Segmental analysis of the degradation of *bla* mRNA in *E. coli* growing in L-broth, MOPS/glucose and MOPS/acetate was performed as previously described⁹. Half lives were determined by densitometric analysis of autoradiograms. Rates of decay were calculated by least-squares determination of the slope of a plot of -ln (band intensity) against time. Errors were estimated from the standard deviation of the slope. For the *bla* transcripts, the half lives of only three of the seven characteristic segments⁹ are reported.

ate¹; in these media, the cells doubled every 40, 100 or 200 min respectively. The decay of *ompA* mRNA, and of its component segments, after the blockage of transcription by rifampicin was analysed by S₁ nuclease protection as described previously⁹. Figure 1 and Table 1 show that the half life of the *ompA* transcript, as judged from the stability of its least stable segment, fell from about 15 min in cells cultivated in L-broth (doubling time, 40 min) to about 4 min in cells cultivated in MOPS/acetate (doubling time, 200 min). Nutritional conditions that led to an intermediate growth rate (MOPS/glucose; doubling time, 100 min) resulted in an intermediate stability for the *ompA* transcript. The retardation of decay reported previously for the segments of the *ompA* transcript nearest the 5' end⁹ was not observed at the slow growth rate. In MOPS/acetate, all segments of the transcript showed approximately the same rate of decay (Table 1). This degradation pattern exhibited by the *ompA* transcript in bacteria grown under conditions that lead to an extended doubling time presumably results from a failure of the cells to accumulate decay intermediates, as observed previously for *bla* mRNA. We have proposed that such a decay pattern reflects rate-limiting initial cleavage of the full-length transcript⁹.

These measurements of mRNA half life rely on the fact that almost all (>95%) of the total RNA in *E. coli* is represented by stable RNA species: that is, ribosomal RNA and transfer RNA¹¹. Because these abundant and stable RNA molecules do not decay to any significant extent during the time course of an experiment for determining mRNA half life¹², they provide a convenient and reliable reference for measuring the rate of degradation of labile transcripts such as mRNA.

Fig. 1 Decay of *ompA* mRNA in *E. coli* cells growing with a doubling time of 40 min (left) or 200 min (right). Total cellular RNA from *E. coli* strain C600 growing exponentially at 30 °C in L-broth (doubling time, 40 min) was isolated 0, 20, 40, 60 and 80 min after rifampicin treatment⁹. Similarly, RNA from bacteria growing at 30 °C in MOPS/acetate¹ (doubling time, 200 min) was isolated 0, 2, 4, 6, 10 and 20 min after rifampicin addition. Segmental analysis of *ompA* mRNA decay was performed as previously described⁹. The bands correspond to the component segments of the *ompA* transcript; the order of the segments (5' to 3') is 200, 85, 598 and 340 nucleotides⁹.

In the absence of any compensatory effect on the initiation of transcription, a reduction in the stability of a transcript should result in a corresponding decrease in its intracellular concentration. Consistent with this prediction is our observation that the fraction of total cellular RNA represented by the *ompA* message falls by a factor of five in cells grown in MOPS/acetate as opposed to L-broth. We also find that the concentration of total cellular RNA, which consists primarily of the stable species rRNA and tRNA, drops by a factor of 1.8 when the bacterial doubling time increases from 40 min (cells grown in L-broth) to 200 min (cells grown in MOPS/acetate), in agreement with previous studies¹¹. Thus, we calculate that the steady-state concentration of *ompA* mRNA is reduced roughly by a factor of nine in bacterial cells growing in MOPS/acetate.

Because the concentration of OmpA protein in cells cultured under different growth conditions is constant¹⁰, the rate of synthesis of the OmpA protein must decrease by about a factor of five as the cell doubling time is increased from 40 to 200 min. The decreased rate of synthesis of OmpA protein that accompanies the prolonged cell doubling time in MOPS/acetate can be accounted for entirely by the observed change in *ompA* mRNA concentration; moreover, most of the reduction in the concentration of the *ompA* transcript can be attributed to its decreased stability.

To determine whether the observed shortening of the *ompA* mRNA half life in cells growing in MOPS/acetate medium is the result of slowed growth rate *per se*, or whether the effect is otherwise related to the media used, bacteria were grown in L-broth until their doubling time began to decrease on entry into the stationary phase. At a stage of growth corresponding to a doubling time of ~200 min, the cells were treated with rifampicin, and RNA was extracted at time intervals thereafter. Under these growth conditions, the half life of the *ompA* transcript was about 4 min, the same half life observed for *ompA* transcripts from cells having a 200-min doubling time resulting from growth in MOPS/acetate medium.

Like *ompA* mRNA, the *lpp* transcript encodes an abundant outer membrane protein (lipoprotein) and has the potential to form extensive secondary structure⁷. However, growth-rate

Fig. 2 Decay of *cat* mRNA in *E. coli* strain C600 containing the plasmid pACYC184 was grown to log phase at 30 °C in L-broth (left: doubling time, 40 min) or in MOPS/acetate (middle and right: doubling time, 200 min), and total cellular RNA was isolated 0, 2, 4 and 6 min after rifampicin treatment⁹. Analysis of *cat* mRNA decay was performed by fractionation of the RNA examples on a 1.2% agarose/formaldehyde gel²² followed by blotting onto a nitrocellulose filter²³ (left and middle). The blots were probed with nick-translated *cat* gene DNA. The decay of *cat* mRNA from *E. coli* growing in MOPS/acetate was also monitored by S₁ nuclease analysis²⁴ (right). Plasmid pACYC184 linearized with *Eco*RI and 5' end-labelled with [γ -³²P]ATP and polynucleotide kinase was used as the probe. The observed protected DNA fragment corresponds to the 5' terminal 270 nucleotides of *cat* mRNA²⁵. The finding of a unique 5' end by S₁ nuclease mapping demonstrates that the two *cat* messages detected by RNA blotting result from multiple sites of transcriptional termination.

dependent alteration of mRNA half life was not observed for the transcript of the *lpp* gene, which had a half life of ~22 min at 30 °C whether the bacteria were grown in L-broth or MOPS/acetate (Table 1). In addition, there was no change in the fraction of total RNA represented by the *lpp* transcript under these different growth conditions. Thus, an increased rate of mRNA decay with the slowing of cell growth is not a universal phenomenon, nor does it seem to be a general property of long-lived *E. coli* transcripts. Although it is not known whether the biosynthesis of the *lpp* gene product is stringently or loosely related to the rate of bacterial growth, our data demonstrate that any down-regulation of the rate of production of lipoprotein is not controlled at the level of mRNA stability.

The effect of growth rate on the stability of two *E. coli* mRNA species having the short half life more typical of *E. coli* messages was also examined. These were the *bla* transcripts of plasmid pBR322, which encode the periplasmic protein β -lactamase, and the *cat* transcripts of plasmid pACYC184, which encode the cytoplasmic protein chloramphenicol acetyltransferase (CAT)^{6,8,13-15}.

There are six overlapping *bla* messages transcribed from pBR322 (ref. 9). These transcripts are initiated at one of two promoters and are terminated at one of three sites. All six *bla* transcripts had a half life of 3 min independent of the growth medium used. Moreover, under all growth conditions, each of the component segments of *bla* mRNA⁹ decayed at the same rate (Table 1). When *bla* transcripts from cells isolated just before entry into the stationary phase of growth were analysed as described above for the *ompA* transcript, the half life was again found to be 2-3 min. As in the case of the *lpp* transcript, the fraction of total RNA represented by *bla* mRNA was the same at all growth rates, indicating that the steady-state concentration of *bla* mRNA fell by the same factor of 1.8 as did the overall RNA concentration in bacteria growing in MOPS/acetate. (The small decrease in *bla* mRNA concentration presumably reflects a slightly reduced rate of transcription.)

In contrast, the intracellular concentration of *cat* mRNA fell by a factor of ~13 when the cell doubling time was increased

Table 2 Enzyme activities of β -lactamase and chloramphenicol acetyltransferase from *E. coli* grown in different media

	L-broth	MOPS/acetate
β -Lactamase	13	43
CAT	0.37	0.25

Enzyme activities are units per mg of cellular protein. All experiments were performed with *E. coli* strain C600 containing either pBR322 or pACYC184. Different growth rates were achieved by growing cells in L-broth or in MOPS/acetate. Bacteria growing exponentially were ruptured by sonication, and the cell debris was removed by centrifugation. The supernatant was assayed for either β -lactamase activity or chloramphenicol acetyltransferase (CAT) activity^{18,19}. Total protein concentration was determined using the method of Lowry²⁰. The copy number²¹ of pACYC184 at the two growth rates was found to be the same, whereas the copy number of pBR322 increased twofold in MOPS/acetate.

from 40 to 200 min. Most of the reduction in *cat* mRNA concentration can be explained by the fact that the multiple transcripts of the *cat* gene, which result from the use of one promoter and two transcriptional terminators (Fig. 2), decayed approximately five times faster in response to the fivefold prolongation of doubling time. The *cat* messages isolated from bacteria cultivated in L-broth showed a half life of 2 min, whereas *cat* mRNA from cells grown in MOPS/acetate medium showed a half life of about 0.4 min (Table 1, Fig. 2).

Analysis of the activities of β -lactamase and CAT in cells growing in L-broth or MOPS/acetate shows that the concentrations of both enzymes, relative to total cellular protein, are altered under conditions of prolonged doubling time. In cells grown in MOPS/acetate, the β -lactamase concentration increases more than threefold, whereas the cellular concentration of CAT falls to two-thirds of its value in L-broth (Table 2). Bacteria grow in MOPS/acetate at one-fifth the rate seen in L-broth; by multiplying these factors, we calculate that the rate of synthesis of β -lactamase must be nearly independent of growth rate, whereas the synthesis of CAT must slow by a factor of ~ 8 in MOPS/acetate. As the steady-state concentration of *bla* mRNA is hardly influenced by growth rate (see above), it is not surprising that the rate of production of β -lactamase is similarly unaffected. In contrast, the substantial decline in the rate of synthesis of CAT in cells growing in MOPS/acetate can be accounted for by the observed decrease in the cellular concentration of *cat* mRNA, which is seen here to result primarily from a decrease in the half life of the *cat* transcripts.

The results reported here indicate that the decay rates of various messages are affected differently by changes in the rate of cell growth. Growth-related effects on decay occur with both a very stable mRNA species (*ompA*) and an mRNA species (*cat*) that has a half life of 2–3 min, as is typical of most *E. coli* mRNAs. The effect of growth on mRNA decay does not appear to be correlated with either the extent of mRNA secondary structure or the nature of the gene product. The *ompA* and *lpp* transcripts both possess the potential for extensive intramolecular basepairing, and both encode abundant outer membrane proteins; yet the decay of only one of these messages (*ompA*) is modulated in response to changes in the bacterial growth rate.

Our observations indicate that control of the rate of mRNA decay is one means by which cells can reduce the rate of biosynthesis of proteins during times of slow growth. Moreover, the finding that only certain *E. coli* messages are degraded more rapidly at slow bacterial growth rates implies the existence of mechanisms that differentially alter the decay rates of transcripts.

We thank Staffan Normark and Ulf Henning for stimulating discussions. These studies were supported by the Riksforskningsnämnden mot Cancer of Sweden and the US NIH.

Synthesis in yeast of a functional oxidation-resistant mutant of human α_1 -antitrypsin

Steven Rosenberg, Philip J. Barr, Richard C. Najarian & Robert A. Hallowell

Chiron Research Laboratories, Chiron Corporation, 4560 Horton Street, Emeryville, California 94608, USA

Cumulative damage to lung tissue by leukocyte elastase is thought to be responsible for the development of pulmonary emphysema, an irreversible lung disease characterized by loss of lung elasticity^{1–3}. It is also thought to be involved in the rapidly developing and usually fatal adult respiratory distress syndrome⁴. The primary defence against elastase damage is the anti-protease known as α_1 -antitrypsin^{5,6}, a glycosylated serum protein of 394 amino acids³. Oxidation of the methionine 358 residue located at the active centre of α_1 -antitrypsin results in a dramatic decrease in inhibitory activity towards elastase which effectively inactivates the protective function⁶. It has been suggested that this oxidation sensitivity has a regulatory function and allows tissue breakdown at sites of inflammation by inactivation of α_1 -antitrypsin by oxygen radicals released by phagocytes³. In the above diseases, however, the oxidative inactivation of α_1 -antitrypsin is probably of major importance in allowing lung damage by elastase^{4,7}. An oxidation-resistant α_1 -antitrypsin might make it possible to reduce the large doses of α_1 -antitrypsin required for emphysemics and provide treatment for acute inflammatory respiratory conditions. To further the possibility of therapy for the above conditions, we describe here the synthesis in yeast of active, non-glycosylated, human α_1 -antitrypsin. Site-directed mutagenesis has been used to construct an active, oxidation-resistant derivative containing a single methionine to valine substitution at the active centre. This demonstrates the potential of engineered modifications to protein molecules designed to improve their physiological function.

To obtain α_1 -antitrypsin cDNA sequences encompassing the entire coding region, a cDNA library constructed from poly(A) mRNA from liver was screened with radiolabelled oligonucleotide probes corresponding to amino acid residues –23 to –17 (25,000 colonies) and 344–350 (5,000 colonies). The probe sequences were taken from the partial nucleotide sequences described previously^{8,9}. Four colonies hybridized^{10,11} to the N-terminal probe and 148 to the C-terminal probe. After gel

Fig. 1 Nucleotide sequence and predicted amino acid sequence of α_1 -antitrypsin cDNA encoding the pre-protein. For expression in yeast the pre-sequence was removed by *Bam*HI digestion. The reactive centre Met-Ser at positions 358-359 is boxed. Amino acids above the sequence identify differences between this protein sequence and those derived from *a*, protein sequencing³; *b*, the cDNA of Woo *et al.* (see ref. 3); *c*, the cDNA of Bollen *et al.*²⁵.

Methods: Double-strand cDNA was synthesized as described previously³⁶, size fractionated on a Sepharose CL4B column to remove most of the cDNA of <300 bp, treated with *S*₁ nuclease and cloned at the *Pst*I site of a pBR322 derivative using the homopolymeric dG and dC tailing method³⁷. Note that the second-strand cDNA was self-primed; the first seven nucleotides of the cDNA differ from the genomic sequence and are probably incorrect as has been described previously³⁸. The following restriction fragments shown were isolated by preparative polyacrylamide gel electrophoresis³⁷: 603 bp *Bam*HI-*Bst*E2 from p5'AT-1; 450 bp *Bst*E2-*Ava*I from p3'AT-11; 85 bp *Ava*I-*Hin*II from p3'AT-3. The five C-terminal amino acids and termination codon were encoded by the synthetic oligonucleotide adapters shown adjacent to the coding sequence. These oligomers were synthesized by phosphoramidite chemistry²⁸, phosphorylated³⁷, and mixed in equimolar amounts. Approximately 2 pmol of fragments 1 and 2 were ligated³⁷ together in 50 μ l and after removal of ligase, digested with *Bam*HI and *Ava*I. Similarly, fragment 3 and the synthetic duplex were ligated and digested with *Ava*I and *Sall*. The resulting fragment mixtures were ligated, digested with *Bam*HI and *Sall* and DNA of ~1,200 bp gel isolated and cloned by substitution into *Bam*HI, and *Sall* cut and phosphatased³⁷ pBR322. Analysis of miniscreen plasmid DNA³⁷ from these transformants indicated that a full length cDNA had been obtained and one such transformant was used in subsequent constructions.

analysis of plasmid DNA from the 4 N-terminal and 12 C-terminal clones, three overlapping clones were selected for further study. We have elucidated a composite DNA sequence for α_1 -antitrypsin derived from the three cDNA plasmids by subcloning and sequencing in M13 phage vectors^{12,13} (Fig. 1). The protein sequence predicted by the cDNA differs from the published sequences in several positions, probably due to the genetic polymorphisms known to be quite common in α_1 -antitrypsin¹⁴.

To assemble a cDNA encoding the mature α_1 -antitrypsin suitable for expression in yeast, three restriction fragments from the *Bam*HI-*Hin*II sites shown in Fig. 1 were first isolated from their respective plasmids. These fragments were ligated together with the synthetic DNA segment shown in Fig. 1 and cloned by substitution between the *Bam*HI and *Sall* sites of pBR322¹⁵.

To construct a yeast plasmid directing the synthesis of α_1 -antitrypsin we first isolated the yeast acid phosphatase (PHO5) promoter from a library of yeast genomic DNA using a synthetic oligonucleotide probe (Fig. 2). The PHO5 promoter was chosen because it is a relatively strong yeast promoter which can be regulated using either phosphate concentration¹⁶ or temperature-inducible mutants¹⁷. The second codon of the acid phosphatase gene was joined in phase to the second codon of the α_1 -antitrypsin cDNA by blunt-ended ligation (Fig. 2). After subcloning, this PHO5- α_1 -antitrypsin segment was isolated as a *Bam*HI-*Sall* fragment and joined to a *Sall*-*Bam*HI fragment containing the transcription terminator of the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) gene (ref. 18 and our unpublished results), followed by insertion into the pC1/1 yeast shuttle vector as a *Bam*HI fragment.

To change the methionine residue at position 358 to a valine residue, we used M13 site-directed mutagenesis¹⁹. The *Pvu*II-

Sall fragment of the cDNA (Fig. 1) coding for amino acids 238-394 was cloned by *Sma*I-*Sall* substitution into M13 mp10¹³. Single-stranded viral DNA was isolated and used as a template for site-directed mutagenesis using a synthetic 30-mer as a mutagenic primer (Fig. 3). Positive plaques were identified using the primer as a probe and the codon change was confirmed by DNA sequencing (Fig. 3). The 360 base pair (bp) *Eco*RV-*Sall* fragment of α_1 -antitrypsin (Fig. 1) containing the mutation, was inserted into the yeast expression plasmid as described in Fig. 3 legend. This fragment was re-sequenced from pC1/1PHO5AT(Val), confirming the T to C transition and showing that no other mutations had occurred during the M13 mutagenesis, as have been observed previously²⁰. Yeast strain AB103²¹ was transformed²² with plasmids pC1/1, pC1/1PHO5AT(Met) and pC1/1PHO5AT(Val).

To characterize the α_1 -antitrypsin produced in yeast, cultures were grown in high (repressing) or low (inducing) phosphate and collected in log phase. Cells were lysed with glass beads, and the soluble cell proteins analysed by SDS-polyacrylamide gel electrophoresis and elastase inhibition assays (Fig. 4; Table 1). The results of the gel analysis (Fig. 4A) show that a protein of ~42,000 molecular weight (MW) is specifically induced in those transformants containing the α_1 -antitrypsin cDNA. A protein of 44,000 MW is expected for mature, non-glycosylated α_1 -antitrypsin. Although strain AB103 contains the *pep*4-3 mutation and is deficient in most of the proteolytic activities of the yeast vacuole²³, additional smaller proteins of ~23,000 and 19,000 MW were specifically induced. These were shown to be antigenically related to α_1 -antitrypsin by Western blot analysis (Fig. 4B) and possibly result from proteolytic degradation. When synthesis of α_1 -antitrypsin was similarly analysed in strain

Fig. 2 Construction of yeast plasmids expressing a PHO5- α_1 -antitrypsin fusion encoding the first two amino acids of the PHO5 gene and residues 2-394 of α_1 -antitrypsin. DNA fragments and plasmids are only approximately to scale. To isolate the PHO5 promoter, the oligonucleotide probe ^{5} GGCACT-CACACGTGGGACTAG ^{3} , complementary to a portion of the sequence of the promoter, was used to screen a library of *Saccharomyces cerevisiae* DNA³⁹. Several positive clones were obtained and one was sequenced^{12,13} and shown to contain the PHO5 promoter. A 630 bp *Bam*HI-*Sal*I fragment from this isolate was subcloned into pBR322. This fragment contains 80 bp of the acid phosphatase coding sequence and has the sequence ^{5} ATGTTTAAA ^{3} encoding the first three amino acids, the second and third codon specifying an *Aha*III site. pC1/1 is a derivative of pJDB219 (ref. 40) in which the PMB9 sequences have been replaced by pBR322.

2150 *pep4*⁺, an increased level of the 23,000 and 19,000 MW fragments was observed as well as the production of a new fragment of 40,000 MW (data not shown).

To determine the activities of α_1 -antitrypsin(Met) and α_1 -antitrypsin(Val), appropriate yeast extracts were incubated with human leukocyte elastase and a synthetic peptide substrate whose cleavage can be assayed by increase in absorbance at 410 nm⁶. Inhibition of elastase was found to be directly proportional to the amount of human α_1 -antitrypsin added in the presence or absence of control yeast extracts (Table 1 assays 1-5, 13, and our unpublished results). Control yeast extracts had no effect on elastase activity (Table 1, assay 6) whereas

Fig. 3 Autoradiogram of the DNA sequencing gel showing the nucleotide sequence of wild-type (Met) and mutant (Val) active centres of α_1 -antitrypsin.

Methods: A mutagenic primer having the sequence ^{5} GACCTCGGGGGGATAGACACGGGTATGGC ^{3} was synthesized and used to prime second-strand DNA synthesis on single-stranded M13 containing a wild-type α_1 -antitrypsin fragment (see text) as described previously^{19,21}. The mismatch is underlined. Mutagenized phage were located using the same primer as a probe and filters were washed for 60 min at 65 °C in 0.15 M NaCl, 15 mM sodium citrate (1×SSC). To substitute the Met to Val mutant in the yeast expression vector shown in Fig. 2, the 360 bp *Eco*RV-*Sal*I fragment of α_1 -antitrypsin (Fig. 1), containing the mutation, was prepared from a digest of the M13 replicative form DNA. This was ligated to the 1,350 bp *Bam*HI-*Eco*RV fragment, containing the PHO5 promoter and N-terminal residues of α_1 -antitrypsin, prepared from pPHO5AT, and the 1,100 bp *Sal*I-*Bam*HI GAPDH terminator fragment, both shown in Fig. 2. After ligation, the mixture was digested with *Bam*HI before ligation into *Bam*HI-cut and phosphatased pC1/1. After transformation of HB101⁴¹, one positive clone, analogous to pPHO5AT(Met), was obtained after restriction enzyme analysis of plasmid DNA from 12 clones.

Table 1 Effects of *N*-chlorosuccinimide oxidation on α_1 -antitrypsin activity in yeast extracts assayed by inhibition of elastase activity

Assay no.	Plasmid	Volume of yeast extract (μl)	μg α_1 -Antitrypsin	NCS (μl) (10 mM)	Elastase activity (%)

14	C1/1	3.8	1.0	10	84
15	Met	1.5	—	—	8
16	Met	1.5	—	10	93
17	Val	1.5	—	—	20
18	Val	1.5	—	10	18

Yeast extracts were prepared by lysis with glass beads and centrifuged to remove cellular debris³². Extracts were diluted in 50 mM Tris pH 8, 50 mM NaCl. For *N*-chlorosuccinimide (NCS) oxidations, 7.5 μl of extracts were incubated at room temperature for 5 min in 100 μl of 50 mM Tris pH 8, with the indicated amount of NCS (10 mM). Aliquots were transferred to tubes containing 0.1 mM Meo-Suc-Ala-Ala-Pro-Val-*p*-nitroanilide (Vega), 50 mM Tris pH 8, 0.5 M NaCl, 100 μg bovine serum albumin (BSA), in a volume of 1 ml. Assays were initiated by the addition of 0.15 μg HLE and incubated for 15 min at 28 °C, terminated by the addition of 100 μl of 8 M acetic acid and the absorbance at 410 nm was determined⁶. Protein concentrations³³ were: C1/1, 6.4 mg ml⁻¹; Met, 8.0 mg ml⁻¹; Val, 9.7 mg ml⁻¹. From the amount of human leukocyte elastase (HLE) activity observed, given the protein concentration of the yeast extracts and the amount of HLE added, the percentage of the yeast-soluble protein that is α_1 -antitrypsin can be calculated. We assume 100 % HLE activity, a 1:1 complex between HLE and α_1 -antitrypsin, and that the molecular weights of HLE³⁴ and α_1 -antitrypsin are 29,000 and 42,000 MW, respectively. In this experiment α_1 -antitrypsin is 3.0 and 3.5 % in the Met extract (assays 7 and 8) and 2.3 and 2.6 % in the Val extract (assays 9 and 10).

Fig. 4 α_1 -antitrypsin (α_1 AT) and related proteins synthesized in yeast. **A**, SDS 10–20% polyacrylamide gradient gel⁴² stained with Coomassie blue showing soluble proteins synthesized in: *a*, uninduced pC1/1-containing control cells; *b*, induced pC1/1-containing control cells; *c*, uninduced pC1/1PHO5(Met) cells; *d*, induced pC1/1PHO5(Met) cells; *e*, uninduced pC1/1PHO5(Val) cells; *f*, induced pC1/1PHO5(Val) cells; *g*, glycosylated α_1 -antitrypsin from human serum. **B**, Proteins from gel **A** which react specifically with antibody to α_1 -antitrypsin. Identical extracts were electroblotted on the same gel, transferred to nitrocellulose paper and α_1 -antitrypsin-related proteins visualized by antibody-conjugated horseradish peroxidase staining⁴³. Elastase inhibition assays (Table 1) indicated that induced extracts contained 1.0 % α_1 -antitrypsin in this experiment.

Methods: Yeast cells were grown in 50 ml cultures of leu⁻ selective media in high or low phosphate to an A_{650} of ~2. After lysis³², ~20 μ g of the soluble proteins were electroblotted on a 10–20 % SDS-polyacrylamide gradient gel and blotted onto nitrocellulose paper. α_1 -Antitrypsin-related proteins were visualized by washing the nitrocellulose paper with rabbit anti- α_1 -antitrypsin (Accurate Chemicals) followed by horseradish peroxidase/goat anti-rabbit antibody staining⁴³. Media containing high and low levels of phosphate consisted of synthetic complete medium lacking leucine⁴⁴ supplemented with 0.2 volumes of phosphate-depleted YEP medium⁴⁵, 2 g l⁻¹ asparagine replacing (NH₄)₂SO₄, 1 g l⁻¹ KH₂PO₄ (high phosphate) or 1 g l⁻¹ KCl, 0.03 g l⁻¹ KH₂PO₄ (low phosphate). Yeast strains are AB103.1 (*Mata leu2-3,112 ura3-52 pep4-3 his4-580* [cir^o]) and 2150-2-3 (*Mata leu2 ade1* [cir^o]).

induced yeast extracts for α_1 -antitrypsin(Met) and α_1 -antitrypsin(Val) both inhibited elastase activity (Table 1, assays 7–10). The percentage of α_1 -antitrypsin in yeast extracts (Table 1) showed approximate agreement with estimates from SDS-polyacrylamide gels, indicating normal activity of the recombinant α_1 -antitrypsins.

To discover if α_1 -antitrypsin(Val) was oxidation resistant, we treated extracts with *N*-chlorosuccinimide, which converts susceptible methionines to their sulfoxides²⁴. Both the recombinant α_1 -antitrypsin(Met) and a reconstituted control extract containing human α_1 -antitrypsin are susceptible to oxidative inactivation whereas the α_1 -antitrypsin(Val) is resistant (Table 1, assays 13–18).

It has been reported recently that the development of emphysema can be limited by intravenous injection of α_1 -antitrypsin partially purified from human serum²⁵. Although this enzyme is the most abundant anti-protease in human serum (~1.3 g l⁻¹)²⁶, insufficient amounts are available from plasma to treat all affected individuals because its half life is only 6 days²⁷. Production from yeast cells offers a viable alternative, especially as yields of >10 % of soluble cell protein as α_1 -antitrypsin have been obtained recently using the glyceraldehyde phosphate dehydrogenase promoter²⁸ (manuscript in preparation). It will, however, be important to establish whether the half lives in serum and the rates of inhibition are comparable for the non-glycosylated recombinant α_1 -antitrypsins. The replacement of methionine by valine at the active centre of the molecule was based on the observation that a synthetic peptide with this substitution is an improved substrate for elastase²⁹. Recent studies have shown that a naturally occurring arginine substitution at this position lacks elastase inhibitory activity but has gained the specificity of antithrombin III³⁰. Thus, it is important to determine the specificities of any derivatives with therapeutic potential. In addition to providing improved treatment for pathogenic deficiencies of α_1 -antitrypsin, the construction of novel α_1 -antitrypsin derivatives by protein engineering, together with kinetic⁶ and crystallographic³¹ studies, should provide a better understanding of the regulation and reaction mechanism of this important anti-protease.

We thank James Travis for gifts of α_1 -antitrypsin and HLE, James Travis and Robin Carrell for useful discussions, Robert Huber for ref. 31, Qui Lim Choo, Kathy Mead, Bernardita Mendez, Patricia Tekamp-Olson, and other colleagues at Chiron for help with experiments and the manuscript.

Giving 'em the business

W.F. Clocksin

The AI Business: Commercial Uses of Artificial Intelligence.

Edited by Patrick H. Winston and Karen A. Prendergast.

MIT Press: 1984. Pp.324. \$15.95, £14.25.

THE past, it seems, is not always another country. In the 1960s, over-optimistic advocacy by researchers of the nascent field of artificial intelligence (AI) created expectations impossible to satisfy. In the 1980s, spurred by the prospect of serious international competition, we again have enthusiastic promotion of the technology of AI — especially expert systems and “fifth-generation” computers — and it is no less fervent: but this time the promoters move in commercial circles. The passionate propaganda from the marketing men dismays the researcher and perplexes the technical manager; as in the 1960s, the hyperbole obscures a realistic assessment of the true potential of AI technology.

In an attempt to clear the air, a colloquium was called by the MIT Industrial Liaison Program to bring together representatives of the four main groups involved: the academics, who started it all; the investment bankers and venture capitalists; those concerned with industrial research and development; and those in industry who use techniques devised by AI researchers because there is a job to be done. *The AI Business* is a collection of the edited transcripts of the colloquium. The book opens and closes with perspective and summary chapters by the editors. The first chapter sets the scene by placing MIT at the centre of AI research, and by giving a short “history” of the field complete with its own Prehistory, Dawn Age, Renaissance and so forth. The practising researcher may find it difficult to take this chapter seriously, while others may be dangerously misled by such cavalier treatment. Similarly, while the last chapter does a fine job of summing up, and offers some homespun advice on what action should be taken by universities and companies, there is again the tendency to lapse into dottiness, viz., “...strength in Artificial Intelligence ensures strength at everything that Artificial Intelligence can help with. And that may be just about everything”. These two chapters are very much the bread of the sandwich though; the meat is proved by the 16 other contributors.

Although Winston (and later, Minsky) admits to regarding the term “expert system” with a certain amount of scorn, the casual reader will not understand why, for the first section of the book contains six chapters describing some of the best examples of work in the field. Here the practitioner will find accounts of his old friends XCON and DIPMETER

ADVISOR, true products of AI research which have reached commercial credibility not by hype, but by quietly saving their users substantial amounts of money.

The next section, entitled “Work and Play”, contains six chapters on a subject close to the hearts of AI researchers: interactive workstations. Part of AI

Robots on the line — automatic welding on the Robogate system at Fiat's Rivalta plant in Italy.

research is about making computers easier to use, particularly as automated design assistants and as apprentices. This goes much farther than the computer-aided draughting found in industry today. The computer should be a participant in the design process, synthesizing candidate designs that conform to sets of constraints with which the designer experiments. There is a fascinating contribution by Alan Kay, who rambles through a compelling mixture of reminiscence and advice. Other chapters cover commercially available systems for electronic design automation and English-language communications with databases. The overall theme of this section is the life-cycle from basic research to exploitation in the marketplace.

The next section deals with robotics. Mike Brady gives a good survey of the relationship of AI research areas to their application in industrial robotics, while the other two contributions survey real-life industrial applications, giving examples of sensor-controlled robots and more general

issues in factory automation. This is the most straightforward and informative section of the book, perhaps as a result of the authors' application of well-understood techniques to well-defined problems, with clear criteria for the success or failure of an application. Other areas of AI are not yet as much under control.

The final section, “Today and Tomorrow”, centres on trends, both technological and economic. Minsky's chapter is a prolonged snort of disapproval at contemporary events in research, politics, business and industry. His basic message, though, is of prime importance. The commercial successes of today rely on AI research carried out ten years ago. Because there is practically no basic work in AI now being done, the future may already be lost. This theme is repeated in the other two contributions by investment analysts. Particularly impressive is the cogent and analytical chapter by the economist, William Janeway. Anyone closely involved with recent Government initiatives in “information technology” in any country will find considerable sympathy with Janeway's view that,

The packaging of ignorance by artifice to obtain finance distorts not only the returns actually received by investors. Distortion of research activity in order to obtain finance on such terms is both a professional and a social cost that we in this country seem ill equipped to appreciate.

The main question to be asked of this book is, “Who is it for?”. As the editors point out in the last chapter, the agreements and differences of opinion expressed at the colloquium have been preserved in the book. The transcripts of the informal discussion sessions at the end of each section are particularly effective in this connection. Great stuff for the practising researcher, who will be intimately familiar with the elusive issues involved, and who will thus be in a position to read between the lines. However, the discussions, together with the editors' own contributions, give the book a tone of superficiality and off-handedness which is dangerous and inappropriate for a more general audience. In spite of this, some of the individual chapters are particularly sound, and deserve wider exposure.

I want to see technical managers and engineers becoming acquainted with the issues covered in this book. But I would tell them not to believe everything they read in it. The simplistic, shoot-from-the-hip flavour may be instinctively appealing, but it endangers credibility, and should not be interpreted as solid worldly-wise experience. Despite Winston's “Six Ages of Artificial Intelligence”, 20 years is not a very long time. What we need, above all, is a little patience. □

Ways with MCAs

Karol Sikora

Monoclonal Antibodies: Probes for the Study of Autoimmunity and Immunodeficiency.

Edited by Barton F. Haynes and George S. Eisenbarth.

Academic: 1984. Pp.318. \$45, £33.

Monoclonal Antibodies: Principles and Practice.

By James W. Goding.

Academic: 1984. Pp.276. \$22.50, £17.

THE immune system has evolved into one of nature's most perfect defences. Recognition, memory, specificity and a plethora of effector mechanisms all combine to create a powerful and dynamic defence network. But things can go wrong. In autoimmune disease the immune response turns its attention to host tissues and organs causing self-destruction. In immunodeficient states, whether congenital or acquired, the host becomes susceptible to a wide range of normally innocuous infectious agents as well as to an increased risk of malignancy. The problem in dissecting out the immune system's game plan is the multiplicity of players. Monoclonal antibodies (MCAs) have changed this. These highly specific molecular flags enable the precise identification of the system's components; the lymphocyte.

For the first time in one book, Barton Haynes and George Eisenbarth have brought together a collection of reviews on the use of MCAs in the analysis of immunological disorders. Beginning with a summary of the study of T-cell differentiation using the well-known anti-T-lymphocyte subset MCAs, the book proceeds through a series of accounts of haemopoiesis, thymic differentiation, human hybridoma formation and immunodeficiency. The final four chapters discuss classic endocrine diseases such as diabetes, thyroid problems and myasthenia gravis.

The net result is a rather hotchpotch collection. To the immunologist there is little new that has not been reviewed elsewhere, often by the same authors. The clinician searching for a clearing in the increasingly complex immunological jungle will also be disappointed; haematologists, rheumatologists and endocrinologists will not find much of relevance here to their current practices

More on monoclonals

• *Monoclonal Antibodies to Receptors: Probes for Receptor Structure and Function*, edited by M.F. Greaves. Publisher is Chapman & Hall, price is £35, \$75.

• *Monoclonal Antibodies and Functional Cell Lines: Progress and Applications*, edited by R.H. Kennett, K.B. Bechtol and T.J. McKearn, a sequel to an earlier volume of 1982. Publisher is Plenum, price is \$59.40, £47.03.

and how to improve them. Too much data is presented in many chapters instead of the critical reviews which would have been far more helpful. An exception is the chapter on diabetes, which succinctly covers the role of the immune system in the causation of the disease. The editors might consider using this contribution as a model for an improved future edition.

I can be a great deal more enthusiastic about the second book reviewed here, that by James Goding. Although MCAs were discovered nearly a decade ago, there are few practical guides to the experimenter setting up a monoclonal factory. Goding is a scientist of considerable experience in the MCA business, and has written such a guide, a good one.

After a chapter on the theory behind MCA production, the remainder of the book goes step by step through the various stages of production, purification, radiolabelling, the application of MCAs in assays and in immunohistology also being discussed. Particularly pleasing is the step-wise layout of the various practical

procedures described, together with the extensive reference material provided. Of course, no two workers use precisely the same approach as outlined but for the newcomer to the field the recipes given do provide a starting point.

Surprisingly little information, however, is given to guide the neophyte in choosing which myeloma system to use, often a major stumbling block. Several are mentioned but no comparison between them is given. And there is no discussion of the more recently developed forms of immunization using peptide fragments; by preparing MCAs to peptides synthesized on data predicted from DNA analysis, the circle between gene and protein can now be closed.

Altogether, though, this is an excellent laboratory manual, invaluable to the newcomer to the field. But new editions will be required frequently if it is to remain useful over the next few years. □

Karol Sikora is Director of the Ludwig Institute for Cancer Research, Cambridge, UK.

Climate of quality

J.M. Walker

Climates of the Oceans. World Survey of Climatology, Vol. 15.

Edited by H. van Loon.

Elsevier: 1984. Pp. 716. \$173, Dfl. 450.

FEW books can have had as difficult a gestation period as *Climates of the Oceans*. The first editor died, the second withdrew, and when Harry van Loon took over, in 1974, 11 years after the book was commissioned, only one chapter was available in a form suitable for publication. New authors had to be found for four of the other six chapters and, furthermore, Dr van Loon had to accept the constraints imposed by the editorial decisions of his predecessors. The publishers must have wondered if the book was jinxed. Fortunately, they persevered.

The result is an academic textbook and work of reference worthy of its place in the *World Survey of Climatology* series. Moreover, the book has admirably filled a gap in the literature; until now there has been no authoritative and comprehensive survey of weather and climate over the oceans. For that reason it will find a wide audience, including not only meteorologists, oceanographers and geographers, but also those who need information about marine weather and climate for commercial purposes.

As is almost inevitable in a book of this kind, the chapters vary in length, quality and style, but the overall standard of writing and presentation is high. Paradoxically, given the paucity of observational data from most oceanic regions south of the Equator, the longest

chapters are those dealing with the oceans of the Southern Hemisphere. O Höflich's contribution on the climate of the South Atlantic occupies 191 pages; N.A. Streten and J.W. Zillman's (South Pacific) 167; and J.J. Taljaard and H. van Loon's (Indian Ocean south of 35°S) 97. In contrast, M.A. Einarsson's chapter on the climate of Iceland takes up only 25 pages (and the reader is left to guess why it is included in a book on ocean climates!).

It is regrettable that the book is not as up to date as it might have been. It contains few references to works published since 1980. Indeed in "Climate of the Indian Ocean North of 35°S" by C.S. Ramage, the most recent reference is dated 1975, and in K. Terada and M. Hanzawa's chapter on the North Pacific it is 1974. The obvious conclusion is that contributions were submitted over a period of years and were not subsequently updated. This is a pity, because in the past decade there have been numerous studies of atmospheric behaviour over the oceans, particularly over the North Atlantic, the North Pacific and monsoonal parts of the Indian Ocean. In Ramage's article, for example, there is no mention of the Monsoon Experiment (MONEX), while G.B. Tucker and R.G. Barry (who deal with the North Atlantic) say very little about the GARP Atlantic Tropical Experiment (GATE).

All things considered, however, it is remarkable that the shortcomings of the book are so few. It is a work of high quality and a mine of information and data. For anyone with an interest in the oceans it will be invaluable. □

J.M. Walker is Senior Lecturer in Meteorology and Physical Oceanography at the University of Wales Institute of Science and Technology, Cardiff.

Husbanding resources

Colin P. Groves

Evolution of Domesticated Animals.

Edited by I.L. Mason.

Longman: 1984. Pp.452. £35.

As archaeozoology has evolved into a discipline in its own right, so there has been a surge of interest in the economics of domestic animals and in the possibility of domesticating new species. Until recently there was little in the way of synthesis on the subject, and no general books had appeared since Zeuner's heavily archaeologically orientated *A History of Domesticated Animals* (Hutchinson, 1963). Now, suddenly, there is a rush to fill the vacuum. Two recent books of note have been Juliet Clutton-Brock's *Domesticated Animals from Early Times* (Heinemann, 1981), a general book suitable as an undergraduate text, and Helmut Hemmer's *Domestikation: Verarmung der Merkwelt* (Vieweg, 1983), so far not translated into English but an essential read for anyone interested in the background to and consequences of the domestication process itself.

Now comes this compilation, intended, as the introduction says, as

a single-volume account of the origin and history of domestic animals, species by species, which will not only be a ready source of exact information but will also provide an introduction to the literature.

In other words, it is not a theory-orientated book like Hemmer's, nor a textbook like Clutton-Brock's, but a source book of data and literature.

There are 69 chapters on different species or groups, including some on potential domesticates and some on experiments in progress. The longer chapters are divided into standard headings: introduction (with sections on nomenclature, general biology, and numbers and distribution); wild ancestor; domestication and early history; recent history and present status; and future prospects. The treatment of these various themes is very variable, and reflects the main interests of the authors of the chapters. Bökönyi is an archaeologist; nearly half of his chapter on the horse is taken up by the section "Domestication and Early History". Epstein and Bichard are both specialists in animal husbandry; more than half of their chapter on the pig is "Recent History and Present Status". Many other contributions are similarly weighted; perhaps the most successful and rounded of them are those by co-authors with different specialities (such as the chapter by Novoa, a veterinarian, and Wheeler, an archaeologist, on llama and alpaca), or by single authors who have made one or a group of species their own (the chapter on the dog, by Clutton-Brock;

on the reindeer, by Skjenneberg; and the series on domestic fowl, turkey and goose, by Crawford). There is always at least a nod towards all the statutory topics, though in some instances an author may be way out of his depth: Ryder flounders desperately amid the complexities of the taxonomy of wild sheep, and is not always happy with archaeological concepts (it is surprising to see his apparent unquestioning acceptance of high proportions of juveniles as evidence for domestication in an archaeological context, a line of argument which one would have thought long since thrown into disrepute), but as soon as he starts writing about wool, his lifelong speciality, he is clear, authoritative and a joy to read.

The section on general biology is, one would have thought, pivotal to each chapter, but perhaps because it is part of the introduction it is in most instances disappointingly skimmed over. Some of the best accounts of species' biology are, unexpectedly, in the chapters on minor species (Bali cattle, by Rollinson; yak, by Bonnemai).

My other main criticism of the book is its lack of an overview. Charles Reed does provide an introductory chapter, "The Beginnings of Animal Domestication", but this is of course from an archaeological point of view, and one would have liked to see similar chapters to cover themes such as the biology of domestication; the question of parallel changes in different species as a consequence of domestication; the suitability of different species for domestication; prospects for new domestication; and so on. I may have misunderstood the purpose of the book here, but it seems to me that discussion of such generalities would have been helpful from both a theoretical and a practical standpoint.

When all is said and done, however, it is a pleasure to read experts expounding the mysteries of their art and the book remains a monumental success. It is a compilation of essential data — the only one there is. It deals with all species that have ever been domesticated, or conceivably ever could be: the African elephant is there, the European bison, the onager (though I personally think this ought not to have been included), the ostrich, the crocodile. We have the latest on the cane-rat domestication project from the University of Ibadan group; hamsters and gerbils; snails and oysters; and a fascinating survey of silkworms. Whatever its defects, the book will stand for years to come as an invaluable reference work. It will deservedly find a place in the libraries of universities, animal husbandry and veterinary institutes, archaeology teams, and even many schools. And thank you, Mr Mason, for doing it; because it needed to be done. □

Announcing a new editor
for an important journal

MODERN GEOLOGY

Editor: L. Beverly Halstead,
University of Reading, UK

MODERN GEOLOGY reports experimental and theoretical findings at the frontier of geological research. Original papers, reviews and short communications afford comprehensive coverage of important developments in the earth and planetary sciences. The editor aims to preserve a balanced perspective of the physical, chemical and biological spheres and to identify major trends and areas of growth in the field. To complete its far-ranging coverage, the journal offers discussion and comments on previously published contributions, as well as book reviews. Another attractive feature of the journal is that it includes pertinent colour plates, published at no charge to the contributing author.

Current & forthcoming papers:

Hot Dry Rock Geothermal Exploitation in the United Kingdom, A. S. Batchelor. Facies Evolution in the Gulf of Suez Area: Sedimentation History as an Indicator of Rift Initiation and Development, B. W. Sellwood & R. E. Netherwood. Early Cretaceous Insects from Southern England, E. A. Jarzembowski. Devonian and Carboniferous Tetrapods — A Global Overview, M. J. Boyd. Molecular Organic Geochemistry — A Tool for the Geosciences, G. Eglington.

Pollination renewed

Peter D. Moore

Pollination Biology. Edited by Leslie Real. Academic: 1984. Pp.338. Hbk \$49, £36; pbk \$19.50, £15.

"FIGS, yuccas and specialized orchids have proved to be the exception rather than the rule." Thus Peter Raven introduces this compendium of review papers in pollination biology as he seeks to emphasize that it is a subject in which great changes are taking place. The period of descriptive work, from which the extraordinary stories of host-specific fig wasps and yucca moths emerged, is now past and experimental research on population variation and the selective advantage gained by specific individuals with particular attributes has begun.

As in most areas of ecology, the direction in which pollination biology is heading is towards a search for generalities rather than specifics. Can one, for example, make general statements about the evolution of breeding systems in plants in relation to pollination mechanisms? Can one quantify the degree of competition between plants for pollinators? Or is it possible to assess the adaptive significance of a specific trait, such as flower colour? These are the sort of problems which the book addresses.

The approach is radical, in places almost iconoclastic. Many old and well-engrained dogmas are critically examined and discarded, though they are not always replaced with simple alternatives. Take the evolution of dioecy, for example. It has long been assumed that the separation of sexes on to different plants provided advantages in terms of out-breeding. Here Wyatt claims that this principle is not supported by experimental evidence, but what does account for the development of dioecy is still somewhat obscure. Perhaps it is a matter of resource allocation, sexual selection or predation avoidance.

A chapter by Stephenson and Bertin is devoted to sexual selection in plants and approaches the subject in a logical way by dividing it into two categories: (i) competition between members of one sex for reproductive access to the other sex and (ii) choice of a partner by one of the sexes. Too often these groups have been confused in botanical studies; it is not difficult to understand how males may compete for access to females, but less easy to visualize the element of female choice. The latter is perhaps best regarded as non-random fertilization following pollen deposition, that is, some form of incompatibility. But this is questionably comparable to mate selection in animals. There is also the possibility that the female can favour specific male plants or pollinators by such characteristics as a restriction of flowering time. An interesting outcome of these processes is that sexual selection in plants

has not led to the visually obvious secondary sexual characters found in animals, but may often have influenced non-visual, physiological and biochemical developments.

This is a book which tackles many topics of interest to geneticists, ecologists and palynologists. Under what circumstances is wind pollination advantageous? What sensory stimuli determine the foraging behaviour of a pollinating insect? How does the density of a population of flowering plants affect the frequency of visits from a pollinator? These are exciting questions which cut across the boundaries of traditional disciplines.

Viewed as an undergraduate text, which it claims to be in part, the book is not

entirely satisfactory. The text is laden with multiple citations; too many subjects are discussed from different angles in separate chapters; and summaries of chapters are often inadequate as a guide to chapter content. But as a source of information and, above all, stimulating ideas for specialists and research workers, this is an extremely valuable addition to a literature which is currently dominated by detail and description rather than a conceptual approach. Figs and yuccas may be the exceptions, but the mundane may yet prove to be even more enthralling. □

Peter D. Moore is Reader in Ecology in the Department of Plant Sciences, King's College, University of London.

Wholesome genetics

Nick Proudfoot

Eukaryotic Genes: Their Structure, Activity and Regulation.

Edited by N. Maclean, S.P. Gregory and R.A. Flavell

Butterworths: 1983. Pp.474. £52, \$99.95.

THE explosion in our understanding of the structure and function of eukaryotic genes is nearly matched by the explosion in books describing it. However, it would seem that Maclean, Gregory and Flavell have produced one of the best accounts yet of the subject.

Far from being a disparate collection of short articles in incompatible styles (as is so often the case), the different reviews contained within the book have been carefully stitched together, in relatively homogeneous and concise format. Another valuable feature is that most of the material is up to date, to 1983, though such praise obviously applies more to some chapters than others. Before each section (group of related reviews), an introduction or summary has been provided. Some of these attempts to be enthusiastic to the extent of light-heartedness; for example: a "collection of DNA segments... has been called either a library (for the intellectuals) or a bank (for the businessman)". I idly wonder which editors refer to gene libraries or gene banks!

My detailed estimation of different sections in the book is as follows. In Section I on gene regulation (which would have been better named "Structural Aspects of DNA in Chromatin"), the first review by Jean Thomas is, to my mind, excellent; it told me all I felt I needed to know about this somewhat biophysical end of the subject. The other two reviews here, dealing with non-histone proteins and DNA modification, are somewhat less useful, though this probably reflects the fact that we know rather little about the involvement of, for example, HMG proteins and DNA methylation in gene regulation.

Section II might again have been more appropriately entitled, this time "Organization of 'Unusual' Chromosomes in Eukaryotes" rather than the general title "Organization of Chromosomes". However, the reviews on mitochondrial, lampbrush and polytene chromosomes are very helpful — so many molecular biologists are familiar with various "classic" experiments carried out using these systems but don't really understand their biology.

The third section covers experimental approaches. I found it somewhat disappointing. Why no specific articles on *in vitro* transcription, transient expression and stable transformation of cloned genes? Indeed, the only chapter I felt enthusiastic about here was that discussing the oocyte-egg system. Not that a review of teratocarcinoma and its use in studying gene expression isn't welcome; it is just that more generally-used systems should have had priority.

Section IV on specific gene systems is clearly excellent; while the order of the reviews is again a bit strange, there is here a wealth of information hard to glean in total from other sources. The book ends with a pathetically (and regrettably) short section on plant genes, but its brevity is hardly the fault of the editors. Taking away yeast, which in any case is barely a plant or indeed a eukaryote, very little progress has been made. Perhaps this will encourage more of us to turn to plants. After all, as Goldberg says in his review, plant genes have all the familiar boxes in

TATA, Cap, GT, AG, AATAAA,

so that one could still feel a "mainline molecular biologist".

Both advanced students and more experienced researchers will benefit from reading this book. I suspect it will find a sizeable audience, large enough for the publishers seriously to consider bringing out a cheaper edition. □

Nick Proudfoot is a University Lecturer and Tutor in Biochemistry at Brasenose College, University of Oxford.

From ecosystems to electrophoresis

New products covered this month include a completely sealed ecosystem being offered as a "gift item" and a computerized densitometer for electrophoresis.

● The use of linear roller bearing action in the new Shandon Hypercut rotary microtome is claimed to ensure a light, smooth cutting operation without sacrificing durability. This feature enables the operator to maintain a controlled cutting speed, producing sections of wax-embedded tissue blocks of an even, consistent thickness in a range from 0.5 to 30 μm . The Hypercut comes complete with a universal knife holder which features a unique lateral adjustment and accepts a wide range of knives, including glass, tungsten carbide tipped and disposable types.

Circle No. 100 on Reader Service Card.

For remote recording, the Hollis GeoPod.

● The GeoPod 124 data acquisition module is a long-term, magnetic tape cassette recording system designed for service in the field and in harsh industrial environments. Used in conjunction with its accompanying tape reader, the M-800, the GeoPod 124 is compatible with the IBM PC, DEC and other computing systems. Suggested uses for the GeoPod 124, from Hollis Geosystems, include meteorology, monitoring conditions on gas pipe-lines, hydrology, and structural strain measurements.

Circle No. 101 on Reader Service Card.

● New from Link Systems Ltd, the AN10000 microanalysis system is capable of measuring, storing, analysing, displaying and manipulating X-ray and electron signals produced by scanning and transmission electron microscopes. The basic 256K central processor is fast, flexible, and operates within a purpose-designed disk operating system which incorporates Winchester technology hard disks as a standard feature. AN10000 is equipped with a high resolution colour monitor, used in conjunction with a keyboard and MOUSE. The latter gives the operator a high degree of control and selection over displayed information.

Circle No. 102 on Reader Service Card.

● Simultaneous determination of nitrogen, carbon and sulphur is possible using two new versions of the Carlo Erba NA 1500 automatic nitrogen analyser. Samples of up to 100 mg (depending on sample composition) can be analysed. Other features are the short analysis times (3 min for N, 5 min for N and C, 6 min for S and 8 min for N, C and S), the wide measuring range (from 100 p.p.m. up to 100% for N, C and S) and high accuracy (better than 0.2%).

Circle No. 103 on Reader Service Card.

● Quickly changed, non-breakable, chemically inert fluoroplastic capillaries are used as the disposable tips for the new Oxford pipettes. Called the Ultra Micro, this series of five pipettes is designed to provide relatively high reproducibility and accuracy at 1, 2, 3, 4 or 5 μl . Both top and bottom of the internal air displacement chamber are sealed by O rings, for leak-free operation. Fluoroplastic (FEP) capillary tips can be used for tasks such as stirring a sample into a cuvette without fear of tip breakage. And it only takes a few seconds to change tips.

Circle No. 104 on Reader Service Card.

● The latest scanning electron microscope from the Electron Optics Group at Philips guarantees 5 nm resolution at 30 KV with 4 nm easily attainable. The SEM 515 attains higher resolution results from improved gun geometry, which gives a better signal-to-noise ratio. In a special low kv configuration this provides a fivefold increase in brightness when compared with the standard configuration. A new feature is the opportunity to include microprocessor-controlled automatic focusing and astigmatism correction. Based on algorithms developed by the Philips research laboratories in Hamburg, fully automatic focusing and astigmatism correction can be achieved in the most difficult circumstances.

Circle No. 105 on Reader Service Card.

● Malvern Instruments' new Zetasizer II is designed to measure the surface charge on particles suspended in liquid media and also to analyse their size distribution. The sizer makes use of high-speed digital correlation analysis of the light scattered by the particles as they move under the influence of an electric field. The charge on the particles is automatically computed and displayed. Particle size measurement — in the range 10 nm to 3 μm — is based on analysis of Brownian motion of the particles.

Circle No. 106 on Reader Service Card.

● A digital storage oscilloscope, data acquisition and waveform analysis system — the Computerscope — is being offered by Advanced Instrumentation & Measurement Systems Ltd (AIMS) of Oxford. The system upgrades a general purpose microcomputer for use in high-speed data acquisition and analysis. The Computerscope includes all hardware and software necessary to convert a common microcomputer into a multi-purpose instrument at a much lower cost than traditional "stand alone" instruments that incorporate their own pre-programmed microprocessor. There are two models. The HR14 has up to four channels with a maximum sampling rate of 500 kHz at 14-bit resolution (0.006%) and Model D2 has two channels and a maximum sampling rate of 3.5 MHz at 8-bit resolution (0.4%). The Computerscope can also operate as a spectrum analyser or signal averager.

Circle No. 107 on Reader Service Card.

Shrimps and foliage share an EcoSphere.

● The glass globe above, little bigger than a softball, is an "EcoSphere". Engineering & Research Associates, Inc. (SEBRA) has taken a concept developed by space scientists and produced a "small-scale model of life on Earth". EcoSpheres are primarily intended as gifts but schools and museums have expressed interest in the EcoSphere as a teaching tool. The sphere contains a system including live shrimps, but the glass sphere is completely sealed, with no "breather" tube to supply exogenous oxygen.

Circle No. 108 on Reader Service Card.

Isco's new pump, the WIZ.

● WIZ RP from Isco is a chemically inert, high precision reciprocating pump which features microprocessor control. It has been designed for applications requiring precise metering at moderate pressures (100 p.s.i.) or for corrosive liquids and organic solvents which can damage peristaltic tubing. After initial calibration, any flow rate keyed in ml per hour (up to 7 litres per hour) will be produced with 1% accuracy. In the dispense mode, WIZ RP delivers any keyed-in volume. As a diluter, it takes up any volume of sample on a first push, and dispenses it followed by any volume of diluent on the second push.

● A new range of vacuum ovens, with volumes from 11 to 138 litres, is now available from Heraeus Equipment Ltd. Ovens in the new VTR series have an easy-to-clean cylindrical inner chamber which is built into a rectangular outer unit, allowing the ovens to be stacked. The large circular window in the door gives a clear view of the inner working chamber, the window itself being made of 15-mm toughened glass. The ovens feature an easy-to-read shelf thermometer, and shelves which can be heated individually are available as an option. These new ovens are designed specifically for sensitive materials which need to be dried at lower temperatures, offer shorter drying times and avoid decomposition or oxidation of the material being dried.

Circle No. 110 on Reader Service Card.

● A completely modular line of preparative scale columns and accessories intended to simplify scale-up of chromatographic separations has been introduced by LKB. The LKB 2237 preparative-scale columns and accessories enable the user to custom-design a preparatory or production-level system to handle working volumes of aqueous or organic solutions in the 0.2–10 litre range. Two series of 2237 columns are available — one for aqueous solvent and one for organic solvent. They enable all of the buffers and solvents required for even the most complex purification schemes, such as those for certain peptides, hormones and lipids, to be used. Columns are available in two diameters (5 and 10 cm) and three lengths (60, 100 and 120 cm) and are autoclavable.

Detachable connection to a Bibby filter flask.

● Filter flasks in the new range from J. Bibby Science Products Ltd can be fitted with detachable connectors to enable tubing to be connected to the flasks without excessive hand pressure. The detachable tubing connector has a silicone rubber sleeve which pushes into the flask aperture. A screwcap then tightens up against the sleeve expanding it so that it provides a firm, leak-free seal. The new flasks are available in Pyrex borosilicate for general use or Quickfit for use with other Quickfit jointed ware. Capacities are from 100ml to 5 litres in Pyrex and 100ml to 1 litre in Quickfit.

Circle No. 112 on Reader Service Card.

The Diastar pathologists' microscope.

● Diastar is a new pathologists' microscope from Reichert-Jung which can be used in conjunction with a new fully automatic, microprocessor controlled camera system, the Photostar. All functional and numerical data are entered via a keyboard into the microprocessor and alphanumeric LED displays are used. Photostar offers automatic film advance, multiple exposures on one frame; automatic matching of exposure to film characteristics; uniform background density on panoramic photographs and automatic exposure adjustment to take account of film or specimen characteristics. The Diastar can be adapted for multiviewing for up to five persons.

Circle No. 113 on Reader Service Card.

● Appraise is a computerized densitometer system for use with electrophoresis. Automated scanning provides programmable automatic step-over from track to track of all common electrophoresis media, and focused slit ultraviolet eliminates cross-talk and sample degradation. Appraise can also check calibration of absorbance and fluorescence. A detailed display of each pattern can be shown on the CRT for preview, and the unedited scan can be restored and displayed. Appraise, from Beckman, provides instant access to 10 programmable test selections and random access and viewing of 20 patterns without rescanning.

Circle No. 114 on Reader Service Card.

● Dynatech Laboratories' range of immunoassay plates includes conventional 96-well MicroElisa format plates ('U' or flat bottom) and also Removawell/Removastrip holders for use with either Removawells or Removastrips. These enable the operator to 'tailor-make' a plate using only as many wells or strips as necessary, and enable savings to be made in the use of antibody/antibody sensitization solutions.

What to do to help in India

Mrs Indira Gandhi's assassination is unlikely to see a retreat for support for Indian science. But in the turmoil, it may be neglected. People elsewhere should do more than they think possible to help.

THOSE who believe that the scientific community is in some sense international had better pay special attention to the plight in which Indian scientists will now find themselves. The assassination last week of Mrs Indira Gandhi will be, for them, more than a mere political calamity. The scientific enterprise in India, whatever its faults may be, owes its growth since independence from the British in 1947 to the policies deliberately followed first by Jawaharlal Nehru, the first Prime Minister of India, and then by his daughter. Their objectives were open and straightforward. Understanding the natural world would in due course be a source of economic prosperity, social improvement and the banishment of superstition.

It is ironical that the most striking proof so far of the wisdom of this policy, the new prosperity of the cereal-growing regions of northern India, may have helped to stir the fears of the fundamentalist Sikhs that their emotional hold on their followers would be attenuated, thus provoking the fortification of the Golden Temple at Amritsar, the Army's counter-move and last week's hail of bullets. There is no risk that Mrs Gandhi's son and her successor will draw the wrong lesson from this sad sequence of events, and conclude that things have been moving too quickly. The danger is, rather, that the new government will be so overwhelmed with the problems abounding in the wake of the assassination (not to mention the election soon to be held) that it will have neither the energy nor the resources for an enterprise whose benefits will be delayed beyond tomorrow.

That is why this is a time for recognizing once more the immediate social benefits to contemporary India of its scientific establishment. This huge country, which is in reality six or seven countries, suffers from a curious sense of lacking a cultural identity. Regional diversity is only part of the trouble. Mrs Gandhi may have been right in complaining (see page 93) that outsiders have no perception of how the long occupation by the British impoverished the country.

For at least a century, the intellectual life of India has been profoundly influenced by the universities, originally created on the pattern of the University of London in 1857. Over the years, the system has generated a distinguished roll of intellectual heroes, whose names are widely known and who are generally respected. The difficulty, for India, is that the achievements of these heroes are in a foreign idiom, one that may even be held to have been imposed from the outside. Part of the Nehru-Gandhi commitment to science and technology may be explained by the need to make a distinctive mark. That, certainly, is why centres of excellence are scattered through India. And the commitment had already gone so far, before independence, that the brief Janata government of the 1970s found it impractical to aim at what it foolishly supposed to be simpler goals. Having come so far, India cannot go back — which does not imply that chairmen of atomic energy commissions should not be sanskrit scholars on the side, or that the distinctive Indian sense of kinship (with places as well as people) need diminish.

The scientific enterprise also has much to offer in the solution of other problems rife in contemporary India. Since the time of Homi Bhabha, in the 1950s, the government of India has been dedicated to the belief that scientific enterprises would help to teach the country as a whole more productive ways of working. The Atomic Energy Commission was the spearhead of this move-

ment, and has now spawned a host of other institutions in the same or a similar mould — from the space programme to superb medium-sized laboratories such as the Physical Research Laboratory at Ahmadabad. The commission's plans for building nuclear power stations may have been less realistic than it had been hoping, but it has offered India a lesson now being widely learned — that difficult technical tasks can be carried through by people who are resolute enough, and meticulous, that it is not necessary in the process that each qualified person's hands should be held up by a small army of assistants and that it is possible for very large projects to be carried through without the corruption endemic in much of India's commercial life. The enterprise is a model of how to get good things done.

In principle, the scientific enterprise is also a model for the cure of that common if less corrosive social disease in India — the bureaucracy that seems to flourish everywhere. The difficulty is inescapable in a democracy where procedures derive from law, but need not be as much an impediment as it is in India. The difficulty has become a serious problem chiefly because those who operate the procedures derive power and therefore pleasure from the processing of pieces of paper that determine what other people should do. The scientific enterprise, however, recognizes that it cannot flourish when hamstrung in this way, and has in many places been able to make a dash for freedom. That is another model that the new government needs to have to hand.

Successive Indian governments' commitments to the goal of self-reliance (potential self-sufficiency) is more controversial. The late Lord Blackett found himself in hot water when he declared, when delivering the first Nehru Memorial Lecture in New Delhi, that it would be prudent for India to take fuller advantage of the willingness of people and governments elsewhere to help with the innovation then so plainly necessary. The shock is still remembered. There is something in the view, which Mrs Gandhi held, that a country as potentially powerful as India cannot perpetually be beholden to others. But may this not be a time when a softening of the line would be wise, if only to allow those who wish to help have something they can do?

The problem of the poor is different. Nobody denies the opinion general in India that a person is not less deserving of respect because he or she happens to be illiterate. But can such a person be as dispassionate, and as solid a member of society, as India's ambitions for democracy would require, if he is more likely to be hurt by infectious diseases or natural catastrophes? India may be lucky not have driven bulldozers through its villages in some rash attempt to make the country modern, but it is hard to believe that the enrichment of the poor would be calamitous. Ironically, there are many in the technical community of India anxious to do more, as Mrs Gandhi, to help with the rural poverty. Is this a time to catalyse their energies?

Governments swept into office in tragic circumstances such as those in India now are of two kinds — those who change nothing for fear that any change will bring more tragedy and those who recognize change to be a way of leavening a sense of shock by a sense of hope. Pandit Nehru and then Mrs Gandhi were persuaded that their scientific enterprise would indeed engender a better India. Their successor would be readily applauded if he were to ask for still greater efforts from those with whom rests the future of Indian agriculture, health and industry.

Outside India, there is also much that can be done. A critical account of science in India (*Nature* 308, 581;1984) provoked a stream of entertaining correspondence with a single theme — how much more Indian scientists (at home and overseas) might do to help India if they had a chance. May not this be a time for them to try a little harder? More to the point, may it not also be a time when the colleagues of Indian scientists, in India and elsewhere, should exert themselves more energetically to help? Nobody would pretend activities such as these would quell communal unrest, making it safe for Sikhs to walk the streets again. But both parts of the now divided community will need to know that their divisions will eventually be submerged in a wider unity. Go give a lecture, send a book, write a letter, is too trite for anything but a personal exhortation. Governments in the West can do more, and should, to help the enterprise along. An intelligent woman's death requires no less. □

Europe in the sky

Europe is preparing for adventures beyond the atmosphere, but without much thought.

ONCE upon a time (in the early 1960s) Great Britain was a disappointed space power (as the saying goes), with a design for a rocket launcher (called *Bluestreak*) whose development it could not afford to finish. So what more natural, Great Britain said to its European neighbours, than that everybody should pool resources and set up a common organization (eventually called *ELDO*, for European Launcher Development Organization) to rescue something from the frustrated enterprise? Everybody also agreed that space would be expensive, and so agreed that there should be a common effort on research (whence *ESRO*, for European Space Research Organization). After many adventures (and a great deal of poor management provoked by indecision), the governments of Western Europe decided that one organization would be enough (called *ESA*, for European Space Agency). But all this time, Great Britain knew it could get what it wanted more cheaply by making a deal with its friends across the Atlantic (or with *NASA*, for National Aeronautics and Space Administration, an agency of the US government). But then the time came when the US government was also short of money, wanting to spend every penny it could find on other kinds of rockets, so that it started asking its partners to dig in their pockets as well as its own. But poor Great Britain was by this time really poor and had nothing at all to spend. And so *NASA* flew off with its rich new friends — France, West Germany and Italy. Poor Great Britain had no choice but to set up a committee to ponder what to do.

This is how legend will encapsulate the developments last week, in Britain and on the mainland, in European policy on space. The cause of everybody's difficulty is *NASA*'s request for paying participants in the manned space platform. France, West Germany and Italy have it in mind to reply with a counter-proposal, one likely to satisfy *NASA*'s need to show to Congress that people elsewhere are prepared to help. Britain's trouble is not merely that the Science and Engineering Research Council (*SERC*) which would normally have an important say in such a project, is just now wondering which parts of basic science should be abandoned, but that the government as a whole is having to decide from which of two or three ministries to extract a further £1,000 million of spending money. The mainland, long since impatient, will be exasperated.

The moral in the tale is, however, simple. The Richmond committee (see page 92) has advised *SERC* to throw its lot in with *ESA* because its terms of reference were too narrow to allow a more adventurous proposal. What happens to British space policy in the next ten years is, however, beyond the competence of grant-making agencies. The government, not the council, should now decide what should be done, preferably in concert with its European partners, say what it intends to do and then stick with its decision. Making such a decision would no doubt be hard, but not making one will have even more serious consequences. □

Grandstand medicine

Baboon's hearts are not taboo for people, but medicine which is not essential is wrong.

THE baboon-heart transplant performed on a critically ill infant at Loma Linda Medical Center in California is disquieting. As a medical milestone, to be sure, it is a remarkable accomplishment. Conceivably, it will someday even be a genuine treatment for the 1 in 3,000 infants born with hypoplastic left heart syndrome, the uniformly fatal defect from which the infant in California suffered. Moreover, it is important that the causes of disquiet should not be misrepresented. The need to sacrifice a healthy baboon so that a human infant might live is simply not the ethical dilemma that animal rightists, with an unfailing nose for the sensational, are pretending. A society that overwhelmingly approves of eating animals (other than people) would be even more astonishingly illogical than usual in its reaction to special cases if it were to deny the propriety of using a lower animal to save a human life. And the mere fact that an animal organ is being inserted in a human is an ethical issue only to those whose residue of mythological sentiment overpowers their capacity for rational thought; is there strictly a difference between the use of pig insulin and baboon hearts to make good deficiencies in human beings?

The serious difficulty over the operation carried out in California is that it may have catered to the researchers' needs first and to the patient's only second. Over the past seven years, Dr Leonard Bailey, the surgeon heading the transplant team, has performed 150 such transplants on animals. There can be no doubt that the team was more than eager to try out its technique on a human. Dr Bailey's sincerity and his commitment to helping infants born with this and other tragic birth defects is above reproach. But it is fair to ask if this was the time to extend what Dr Bailey himself calls a "highly experimental" operation to humans.

It is not reassuring that the Loma Linda hospital did not even check with the California Regional Organ Procurement Agency to find out if a suitable human heart was available. (As it turned out, one was; it is not known whether it would have proved

compatible.) It is less reassuring that hospital spokesmen first said they had not known that a human heart was available, and then claimed that in any event it would have taken five days to match the tissues of donor and recipient. (According to researchers at Stanford University, a major centre for heart transplants, the procedure takes only eight hours.) Bailey then acknowledged that a human donor had not been sought because, simply, the purpose of his experiment was to see if the baboon heart would work.

Bailey has been given approval and has been promised support from Loma Linda to perform five more baboon-heart transplants on human subjects. One can only hope that before the next operation, the hospital will agree to release its protocols for the operation and copies of the informed consent forms that parents are asked to sign; so far the hospital has refused to do so. This is not nitpicking; although the research is privately supported, Loma Linda should feel an obligation to the scientific community if not to the public as a whole to provide reassurance. Otherwise suspicions will arise that its researchers are playing to the grandstands. □

French research

New minister plans for selectivity and flexibility

Paris

M. HUBERT Curien, newly-appointed minister of research and technology in France, is preparing to make French science policy really work.

For three years, French scientists have enjoyed close attention, encouragement and even cash from a government which saw — and still sees — science as the nation's salvation. But the economic results have been disappointing, and major government programmes in biotechnology and electronics, for example, have been criticized as substantial failures.

Publicly, Curien does not agree. ("It's difficult for a minister to admit failures", he said in his Paris office last week.) But within the ministry, he is making a careful assessment of the "*programmes mobilisateurs*" set in train by his predecessor, Jean-Pierre Chevènement, in 1982.

Selectivity is the watchword. The trouble with the early dreams was their breadth, all of biotechnology, for example, or all of electronics. But France has only 50 million people and, more tellingly, a history of success in narrow rather than broad technologies such as: nuclear power, space and the high-speed trains. Curien's task must now be to focus the programmes more narrowly.

Curien was previously president of the French space agency (CNES) and of the European Space Agency (ESA), and he recognizes the difficulty. "It is much easier to make good central policy in things like space, where there are few customers and, when you have half-a-dozen programmes, you've covered all the field."

Curien says that while the biotechnology programme did not achieve everything, it created a number of small companies and developed a view of what French industry needed to do. So Curien now has to choose. So far, he has picked agriculture and food, where many of the French traditional industries (such as wine and cheese) are both of great importance to the French economy and in very poor contact with French science. This must change "very rapidly" if the industry is to remain competitive.

In electronics, similarly, there must be rationalization and selection, he says. He cites as promising fields software, where France is already strong, robotics ("we've made some advances") and computer hardware where, says Curien, we should expect a new French product in the mid-range between a microcomputer and a minicomputer.

French researchers should also find themselves with more computers next year, according to Curien. He claims to have cut

the Gordian knot which effectively forbade French laboratories to buy foreign computers while the French industry struggled to catch up. This policy has led to serious under-equipment particularly in nuclear physics groups. But from next year, says Curien, groups will be free to buy computers which are "essential" for their laboratories if they will not be available "in the coming years" in France.

Curien is also seeking more money for industrial research, both from industry itself and from banks. "There is still a large gap between the [1982] plans and reality." France will have to make a "big effort" to catch up with Japan or even West Germany. In the big companies it is a question of rate; in the small, that they do no research at all. The big companies can be influenced from Paris but Curien says the government encouragement of regional science policy is beginning to have important effects on the smaller enterprises. Curien is also consulting the banks about legal obstacles to raising risk capital. In France, a person once bankrupt is forbidden from ever running a business again.

The minister also plans to raise the political temperature of science again next year (cooler now than in the Chevènement years) by staging a major debate on French

research and development in the National Assembly. The topic, ostensibly, will be that of what is to be done in 1985 when Chevènement's 1982 law on the orientation and support of French science comes to the end of its term. "It may be a new law, it may not", says Curien noncommittally. One possible theme is a linkage between the ministry of research and technology and the Administration du Plan, the French ministry that makes long-term "plans" for France with a considerable degree of independence from the president or prime minister — and a sometimes equal independence from effect.

Another key issue for Curien is the old chestnut of finding jobs for young researchers, or the ageing of the research community. So far France has not met the 4.5 per cent recruitment target of the 1982 law but has kept up a respectable 3 per cent; but even this cannot go on, says Curien. "We cannot solve this problem by creating new jobs every year. We must have a real policy." In 10 years the problem will change as the "recruitment bulge" retires but the bulge comes at different times in different agencies so that retirement and recruitment must be managed.

Curien says that making the scientists civil servants (in a new employment contract to be published soon) "will ease the situation". The point is that the new contract will give researchers "a parachute" — a guarantee of their old jobs back — if they shift into something new (such as industry). Curien hopes this will cause movement and, no doubt, that in the end not too many parachutes will have to be used.

Robert Walgate

West German research

Industry favoured by budget

Aachen

THE budget of the West German Ministry for Research and Technology, which forms 70 per cent of the total government civil research budget, is to be increased by 3 per cent in 1985. This is more than the growth in the national budget (1.2 per cent), and reflects the attempt of the government to keep abreast of new technological development.

The distribution of the budget of DM 7,250 million clearly demonstrates the government's intention to promote industrial research efforts. Whereas support for the reactor in Hamm has been reduced by 6.1 per cent, industry will be given increased support, both directly through a 28.5 per cent increase in research subsidies, and indirectly, through a reduction in taxes and financial support for research projects.

Particular encouragement is given to the employment of young scientists by companies with fewer than 3,000 employees and a yearly turnover of less than DM 300 million. Sixty per cent of the salaries of new research staff will be paid

for 15 months when these conditions are fulfilled. Exchange of younger scientific personnel from industrial research laboratories to academic laboratories will also be supported to stimulate transfer of information between the sectors.

In particular, the redistributed budget is designed to assist the foundation of more new technology-oriented companies for which an increase of financial support of nearly 150 per cent is foreseen. Directly supported research institutes, which absorb more than one-third of the whole budget, are expecting an increase of 5.3 per cent. Furthermore, Dr Heinz Riesenhuber, the Minister for Research and Technology, stresses the need for adequate research into the consequences of new technological developments. In the face of the effect of pollution on the forests in Germany, efforts are to be made to evaluate a wide range of developments, from the use of methanol as a fuel to the value of the electronics industry in improving the employment market. A 122 per cent increase in funds for such studies is anticipated.

Jürgen Neffe

NIH budget

Reagan vetoes busybody bill

Washington

EFFORTS by the US Congress to create a new arthritis institute and a new nursing institute at the National Institutes of Health (NIH) have been blocked. President Reagan last week vetoed a controversial NIH reauthorization bill passed in the last few days of the 98th Congress which, besides creating the new institutes, would have required the appointment of disease prevention directors and a formalized NIH policy on matters as different as the use of experimental animals and investigation of scientific fraud. Because Congress is not in session, the so-called "pocket veto" cannot be overridden. In his memorandum of disapproval, the president said the bill would create expensive new organizations, institutionalize over-specific research and place undue constraints on executive branch authorities.

The bill, which had received wide bipartisan support in Congress, was the culmination of a two-year effort by Representative Henry Waxman (Democrat, Los Angeles) to introduce more congressional control over NIH. Waxman last week described as "callous and insensitive" the president's veto of a bill that would "improve our ability to find a cure for cancer, arthritis and stroke".

The reaction at NIH, however, is likely to be one of unmitigated relief. While some of the bill's provisions would merely have added statutory authority to guidelines already in use, others were seen as unwarranted meddling in NIH's internal affairs. The creation of the new institutes was particularly opposed, on the grounds that it would introduce new administrative costs to little effect. The president's veto does not threaten existing NIH programmes, which can continue to operate (as they have since 1980) under the general authority of the Secretary of Health and Human Services to conduct and support research. Congressional aides said after last week's veto was announced that there is still widespread interest in reauthorizing NIH and that the veto will dissuade a future Congress from moving to pass similar legislation. Some predicted that parts of the now-dead bill will be resurrected in a new legislation next year.

The compromise version of the bill that eventually emerged from a House-Senate conference represented a considerable watering-down of Waxman's original proposals. The requirements placed upon institutes to undertake specified kinds of research would nevertheless have had an immediate impact in some instances. The bill would also have established a plethora of statutory bodies to oversee research in different areas. Present regulations on *in utero* fetal research would have been encoded in law, as would the requirement for peer review of research grants.

The bill had included a provision to set up a Congressional Ethics Advisory Commission to study human genetic engineering and fetal research, to have been modelled on Congress's Office of Technology Assessment. Despite last week's veto, preparations to establish an advisory committee of some sort are going ahead: it is not yet clear what sorts of legal authority are required for different functions of an advisory committee.

One of the few parts of the authorization bill that NIH is sorry to lose is that relating to use of experimental animals. The requirements were almost identical with new guidelines already being implemented by

NIH, but a legal obligation to follow the guidelines would have allowed NIH to defend itself more strongly against organizations protesting about the use of animals in research.

The separate appropriations bill for NIH also passed recently by Congress is still waiting for the president's signature. Congress awarded NIH \$5,100 million for fiscal year 1985, an increase of 14 per cent on the previous year, considerably more than the administration's request. There is however little reason for the president to veto the appropriations bill, because a back-up appropriation for NIH included in the continuing resolution provides an identical sum. For the time being, at least, it seems that NIH has succeeded in both having its cake and eating it.

Tim Beardsley

Molecular science

Japan's next target — biology

Tokyo

A THREE-YEAR project to develop in Japan a whole new set of automated tools for molecular biology and cancer diagnosis is about to be launched. The Science and Technology Agency (STA) hopes for rapid government approval for a plan to apply Japan's skills in electronics and precision manufacturing in this field.

Overall expenditure for the project is expected to run to around ¥2,000 million (\$8 million) with ¥618 million (\$2.6 million) allowed for in the first year. The money will come from the special co-ordination funds of the Council for Science and Technology, Japan's highest science policy-making body.

Announcement of the project comes just as Prime Minister Yasuhiro Nakasone has agreed to give top priority to cancer research in next year's budget. Since he gave his approval to a ten-year programme for cancer control last year, several of the science ministers have announced new plans — and new funds — for cancer research (see *Nature* 310, 264; 1984). Now, Nakasone seems to have given tacit approval to an overall 17.8 per cent increase in funds for the next fiscal year.

The overall chief of the new STA project will be Dr Toyozo Terashima, deputy director of the National Institute of Radiological Sciences. There are two main themes: technologies that can directly facilitate research into the molecular biology of cancer, and technologies of use in the diagnosis and therapy of cancer.

In the first theme, attempts will be made to speed up several routine but time-consuming procedures of the molecular biology laboratory. A good part of the research will be performed by industrial companies, in cooperation with university and government research institutes.

Watch-makers Seiko will continue development of an automatic DNA sequencing machine (*Nature* 307, 193;

1984), while film-makers Fuji Photo will improve their new gels for DNA electrophoresis. The chain of events may then be completed by electronics giant Hitachi, trying to develop computerized equipment to read the gel electrophoresis pattern.

Meanwhile, a large chemical manufacturer, Toya Soda, will develop equipment to extract specific DNA fragments from a DNA mixture and tackle the difficult task of building an automatic amino acid sequence analyser. And Japan Electron Optics Laboratory will attempt to develop technology to analyse the three-dimensional structure of protein-DNA complexes using electron beams.

Another goal is to find new ways of introducing DNA into cells: earlier this year, a group at STA's Institute of Physical and Chemical Research (RIKEN) developed a system for opening tiny holes in cell walls using a very brief laser pulse. In the one-second interval before the hole closes spontaneously, DNA from the surrounding medium can enter the cell. Further new systems, using both viruses and very short high-power electric pulses, are now to be tried out by a pharmaceutical company, Dai-ichi Seiyaku. RIKEN and the Tokyo Metropolitan Institute of Medical Sciences will also try new techniques to extract and purify very small amounts of protein produced with the proliferation of cancer cells. New assay cell culture systems for oncogenes will be developed at the Tokyo Medical and Dental University.

In the second part of the project, RIKEN and the National Institute of Radiological Sciences will commence work on the analysis and synthesis of glycoproteins located on the surface of cancer cells, and the Electrotechnical Laboratory on computer tomography for the detection of cancer. Finally, the huge Sumitomo Electric Company is to seek ways of speeding up production of monoclonal antibodies.

Genetic manipulation

NIH concede part of Rifkin suit

Washington

THE US government has quietly conceded a major claim in the lawsuit brought by anti-genetic-engineering activist Jeremy Rifkin to halt field trials of recombinant microorganisms.

Last May (see *Nature* 24 May, p.296), US District Judge John Sirica placed a preliminary injunction on all such experiments supported by the federal government, and in particular an experiment planned by Steven Lindow of the University of California at Berkeley to test the ability of genetically-engineered bacteria to protect potato plants against frost damage. Sirica ruled that in approving that experiment, the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health (NIH) had failed to satisfy two legal requirements: it had not conducted a formal environmental assessment of the experiment, and it had not prepared a much lengthier environmental impact statement on the entire programme of environmental release of recombinant DNA.

In an appeal filed with the US Circuit Court of Appeals in Washington, the government has now indicated that it will prepare an environmental assessment of the Lindow experiment and any others involving release to the environment. The government is continuing to appeal against Sirica's finding that what is called a "programmatic impact statement" is required. In a separate appeal, the University of Cali-

fornia is challenging both requirements.

According to Bernard Talbot, deputy director of the National Institute of Allergy and Infectious Diseases, the NIH institute that contains RAC, attorneys of the Department of Justice had pressed NIH to drop its opposition to the environmental assessment requirement, feeling that the government's case would be much stronger if it were limited to the issue of the future programme. The government argues that there is in fact no "programme" of release to the environment, and that the proposed experiments are so widely different that a case-by-case approach is the only one possible.

The Office of Recombinant DNA Activities at NIH has already begun to compile an environmental assessment of the Lindow experiment, but NIH officials make it clear that they consider the exercise meaningless, fulfilling a formal legal requirement without adding anything of substance. The Lindow experiment was debated at two public meetings of RAC, and was revised in response to concern expressed by the committee. NIH appear to be hedging their bets by agreeing to go ahead with the environmental assessments at this stage. And with the University of California continuing to press the full appeal, the government clearly had little to lose.

Although Sirica's injunction specifically exempted experimental proposals from commercial companies — which have been

What, no uranium?

Canberra

AUSTRALIAN exports of uranium oxide to France are likely to stop for at least two years. The Australian Minister for Resources and Energy, Senator Walsh, announced last month that the first eight shipments of yellowcake that were to have been sent to the French power company Electricité de France under a contract with the Nabarlek uranium producer, Queensland Mines Limited, will be deferred because of the continuation of nuclear testing at the French underground site at Mururoa Atoll, in the south central Pacific.

This is in line with the Australian government's ban on uranium sales to France confirmed during the Labor Party's national conference in Canberra in July, when a vote to continue mining and export of uranium was carried (see *Nature* 2 August, p.354). The first shipment (due in October) would have been 100 tonnes of yellowcake valued at \$A6 million. The Australian government has agreed to purchase the first eight contracted shipments at the original price, but Queensland Mines is obliged to repurchase the uranium "if circumstances permit". This is interpreted to mean if and when the French stop testing nuclear weapons in the Pacific.

Jeffrey Sellar

submitting them to RAC for approval on a voluntary basis only — NIH director James Wyngaarden has ordered that environmental assessments be carried out for these as well. At its June meeting, RAC approved two commercial proposals from Advanced Genetic Sciences (AGS) — almost identical to the Lindow experiment. Once the Lindow document is completed, it should be a quick matter to prepare for the AGS proposal, and that experiment should be clear to go ahead by next spring.

The appeals court is scheduled to hear the case on 5 December. Although the appeal is technically on the preliminary injunction only, for practical purposes the court's decision will decide the entire case. If the appeals court upholds Sirica's decision, the government will probably concede the case rather than let it drag on to a near-certain outcome.

Rifkin was notably unsuccessful on another front last week, RAC unanimously rejected his proposal to ban all transfers of genetic material from one mammalian species to the germline of another. The committee noted the benefits that such research holds for the study of cancer and other diseases. Researchers at the University of Pennsylvania have already successfully inserted the gene coding for human growth hormone into mice embryos, and are planning similar experiments on sheep; RAC also noted the possible benefits that such research would bring in more efficient food production.

Stephen Budiansky

Gloomy outlook for young neuroscientists

Los Angeles

As the US Society for Neuroscience held its 14th annual meeting in Anaheim from 10 to 15 October, there was talk in the corridors of great frustrations and dashed expectations.

But the subject did not revolve around difficult research questions in neuroscience. Rather, it applied to scores of young scientists who are dropping out of the discipline because financial support and job prospects are woefully inadequate.

Neuroscientists are not the only group to complain about support for the students they train. But, argued Dr Dominick Purpura, last year's society president, because neuroscience is reaping great intellectual rewards, it is attracting many of the brightest and best students in US universities.

Once trained, the young neuroscientist is faced with "incredible competition", Dr Purpura said. "Many universities will take on a young scientist for one or two years, whereupon the scientist must provide his or her own financial support. But the young are competing against established people for limited funds. There is so much compe-

tion that people are disheartened and drop out." The job placement centre at the meeting interviewed 1,200 candidates for fewer than 250 jobs, mostly postdoctoral appointments without long-term security.

Unfortunately, few of you will be given the opportunity to use yours....

BIRCH

The National Institutes of Health and the National Science Foundation together support 85 per cent of research in biology and biomedicine, Dr Purpura said. "They are \$50 to \$100 million short in grants that might allow young neuroscientists to get a start."

Sandra Blakeslee

Japanese technology

MITI seeks friends from abroad

Tokyo

JAPAN'S Ministry of International Trade and Industry (MITI) last week took the remarkable step of inviting foreign representatives to attend a joint meeting of two of its key councils concerned with the planning of research and development projects.

A major new bill to promote high technology research is in preparation (see *Nature* 310, 614; 1984), and MITI seems anxious to sound foreign opinion before presenting the bill to the *Diet*. What remains unclear is whether the meeting will turn out to have been a sop to those feeling threatened by MITI's new plans or a first step in an initiative to encourage international research cooperation. For the foreigners, at least, the hope was that this would be the first of many meetings.

The two councils, the Industrial Technology Council and the Industrial Structure Council, between them play the major role in deciding the thrust of MITI's big research and development projects. All too often, these projects have been fiercely criticized by foreign governments for "targeting", or for aiming to use the combined strength of government and industry to achieve Japanese technological domination in some highly profitable area.

Recent projects have evoked strong reactions worldwide. Those under way at the moment include the fifth generation computer project (which has frightened many advanced nations into launching their own "artificial intelligence" programmes); an optoelectronics project designed to rid optical fibre circuits of relay electronics through the use of optical switching; the massive sunshine and moonlight projects intended to exploit new energy sources (geothermal, solar and biomass) and to find new ways of conserving and storing energy; a host of projects on improving industrial performance through use of robots, flexible manufacturing systems equipped with lasers and computerized sewing and garment assembly machines; and long-term projects aimed at new ceramics and superlattice semiconductors.

The first MITI project that really evoked foreign discontent, however, was the VLSI (very large scale integrated circuit) project that ran from 1976 to 1980 and which involved 100 researchers from the seven large computer manufacturers, MITI's own electrotechnical laboratory and the telecommunications monopoly NTT's electrocommunications laboratory. Virtually all aspects of the production of microchips were investigated, seven hundred new inventions were patented and within a year of the end of the project, Japanese manufacturers had seized 70 per cent of the world market in 64K random access memories (rams) and were leading world

research in the production of 256K rams and 1 megabit microchips.

US electronics companies sent reeling by this assault on their markets vigorously protested that the pooling of competing companies' research resources was unfair — particularly as their own anti-trust laws would have made a similar strategy impossible. Japanese companies on the other hand show little respect for the value of the MITI project, and instead attribute success in the world microchip market not to a mythical "Japan Inc." but to the fierce competition among themselves to produce the finished item as cheaply as possible.

Since that time, there have been regular demands from the United States to allow foreigners to act as witnesses, or even participants, on Japanese government research councils. While this may seem unreasonable interference in another government's deliberations, the United States says it seeks only a clear understanding of new legislation before it can cause industrial hostilities. In Japan that means seeing the legislation before it is submitted to the *Diet* which can hardly be considered a major forum for debate when more than

eighty per cent of bills pass without any amendment whatsoever. (The general procedure is that a consensus is worked out behind the scenes before a bill is ever presented.)

In the event, the representatives invited to the MITI councils' meetings — from the United States, United Kingdom, West Germany and France — were from their respective Chambers of Commerce rather than from embassies. MITI itself made no specific proposals, although suggestions have been made that foreign companies operating in Japan may be allowed to use the new industrial technology centre that MITI wants to set up, and that exchanges of personnel may be encouraged in areas in which Japan now leads the world. Foreign representatives were however, given a chance to say how international cooperation might be brought about.

Other attempts by Japan to encourage major international research projects have so far yielded little fruit. The series of proposals made at the Williamsburg summit, such as that for the development of new robots to work in dangerous environments, may have hung fire because they tried to involve all the summit nations. Smaller scale projects arrived at through bilateral agreement may prove more successful.

Britain in space

Strong links with Europe urged

BRITISH scientists and grant-making agencies are urged to play a fuller part in the work of the European Space Agency (ESA) in the report of a committee to consider future policy. The committee, under Sir Mark Richmond, the vice-chancellor of the University of Manchester, also says that its parent, the Science and Engineering Research Council, should take the initiative in persuading government departments to set up a strong coordinating body for British space research.

Among academics working in the field, the overwhelming reaction is relief that the Richmond committee has not advocated a retreat from space research. The same interests complain that the committee has not openly advocated some way of financing space research other than by subventions from the academic research budget. No doubt the committee would have been more explicit if it had some inkling of what the British government would be prepared to spend (if anything).

The origin of the committee, reflected in the arguments of the report now published, is the financial pressure of British space research in recent years. The committee points out that British government spending in the civil field is £80 million a year, compared with £200 million a year in West Germany and £300 million a year in France (the main sponsor of the Ariane launcher).

The committee notes that British scientists have in the past been able to sustain

their research by means of bilateral agreements, chiefly with the United States, largely on the strength of good science and competence in the design and construction of instruments. But this period, the committee says, is drawing to an end, partly because British scientists are no longer outstanding among Europeans, partly because they have less to offer in cash as well as kind, partly because of some recent failures of instruments built for other people's satellites (such as some of the detectors of the EXOSAT satellite) and partly because of a change of US policy, now slanted towards collaboration with ESA wherever possible.

The Richmond committee acknowledges the relatively high cost of international collaboration but says that if British academic science does not intend to abandon space altogether, it should participate more fully in ESA. On particular points, the committee recommends a transfer of the Science and Engineering Research Council's interests in remote sensing by satellite to the Natural Environment Research Council and the encouragement of British industry to interest itself in microgravity experiments.

The Richmond report has not been formally adopted by the Science and Engineering Research Council. The council is probably as embarrassed as the committee by uncertainty about the government's financial intentions. □

European space

Another Franco-German deal

Paris

FRANCE and West Germany have reached "a very good agreement" on collaboration in space and on the European response to the invitation to participate in the US space station, French science minister Hubert Curien said last week.

No figures were discussed between Curien and his German opposite number, Heinz Reisenhuber, when they met in Bonn on Wednesday, but there was agreement in principle that the French should join in with the "Columbus" space station project proposed by Germany and Italy, while Germany would take a share in the HM60 cryogenic motor under development in France for the Ariane-5 space launcher.

Thus it seems that a continental, Franco-German-Italian plan has emerged for a space programme for the European industry in the 1990s, with the other potential major partner, Britain, left on the sidelines. Curien was "sure", however, that Britain would participate "though I'm not certain at what percentage". British government sources have said that the nominal 2 per cent that Britain took in Ariane would certainly be too small.

But whatever share Britain takes, it is clear that European mainland is now calling the tune. No British proposals have emerged that could be traded against Columbus and Ariane-5 to provide a package more suited to Britain. British Aerospace's HOTOL concept of an air-breathing, runway-using hybrid between the space shuttle and Concorde is too distant a prospect to be of use in negotiations, and the proposed free-flying robotic platform may be too like parts of Columbus.

Meanwhile, Europe's space scientists are attempting a defence of their territory, the mandatory science budget of the European Space Agency. In principle, the space station is part of ESA's optional programme. Microgravity and Earth resources research are also optional, coming under the transportation and applications budgets, but the "traditional" space sciences of high-energy astronomy, magnetospheric research and planetary sciences are mandatory to ESA members. Space scientists in this traditional area fear an erosion of mandatory budget — whereas in fact it has long been claimed that it should be increased.

Just by chance, the ESA space science directorate has now come forward with a rational plan as to how that budget should grow. Called the "Horizon 2000" study, it was prepared from 77 responses from the larger space science institutes around Europe to a request for realistic projects for the 1990s. Whittled down by an ESA committee, it is a proposal for a 50 per cent growth in real terms over eight years. The

programme would be based on four cornerstones:

- A solar terrestrial programme (space plasmas)
- A mission to asteroids and comets including return of material to Earth
- A high throughput X-ray mission for spectroscopic studies at 0.1–20 keV
- A high-throughput heterodyne spectroscopy mission to cover the last remaining unexplored region of the electromagnetic spectrum.

Mrs Indira Gandhi

A sharp-witted democrat

Mrs Indira Gandhi, killed last week, had the sharpest wit. I met her at the end of February when her attempt to negotiate a settlement of the Sikh rebellion with community leaders from the Punjab had collapsed. It would have been forgivable that she should have cancelled a meeting with a visiting journalist interested only in her expectations of Indian science. Perhaps she welcomed a chance to talk about something completely different.

Disconcertingly, this did not prevent her from reading and signing her mail while keeping command of the conversation. Occasionally, members of her staff would creep into her office with messages and

would be told what to do by signals, a movement of the hand or eye that did not interfere with the flow of words.

There was an awkward moment at the beginning, when it seemed as if the Prime Minister thought that *Nature* is a magazine devoted to environmental causes; she launched on an eloquent speech about the beauty of the Indian landscape that threatened to use up the 45 minutes available. But, when prompted, she changed the course of her conversation without batting an eyelid.

Quite apart from Mrs Gandhi's belief (taken over from her father) in the importance of research and development in India, she exuded affection for the field and its practitioners — "my scientists" she called them. Her gratitude to people like Professor M.G.K. Menon (who has held

Such missions would not be in competition with United States or Japanese projects, it is claimed, but could be part of a balanced world programme of space research.

The Horizon 2000 study has been very well received in West Germany and Switzerland, where both countries are willing to provide the 7 per cent budget increase a year it implies, but other ESA members are proving more reluctant. M. Curien, for France, says he might find 5 per cent "at a great stretch", and a clutch of other states are talking of a mere 3 per cent. Britain has nothing to say just yet.

Robert Walgate

almost every senior scientific post in the government that there is) was evident. So was her pleasure at having as colleagues people such as Dr T. Koshoo, now Secretary at the Department of the Environment, whom she had inveigled to Delhi over a period of two years.

Mrs Gandhi was astoundingly knowledgeable about the vast programme of research her government mounted. Her willingness to visit laboratories and construction sites was renowned. One consequence was the high morale of those who worked there.

With some of her problems, Mrs Gandhi was plainly impatient. University administrations had let authority slip from their grasp, she implied; they should be more vigorous, more like her perhaps. But then, visitors from overseas should beware of the trap of applying in India the standards conventional in the West. The real wisdom of India rests with the village peasants, hardly any of whom can hope that their children will find their way to a university. It was easy to see how other Indian politicians, allies and critics alike, acknowledged that her electoral strength lay in the villages.

So how to reconcile the poverty with India's ambitions in high technology — nuclear power, space technology, electronics and so on? Mrs Gandhi was eloquent on the theme that a sovereign state as powerful as India could not allow itself to remain in thrall to the West. "Look at what they did to us over the fuel for Tarapur", a reference to the ham-handed administration of the US Anti-Proliferation Act towards the end of the Carter presidency.

Mrs Gandhi's demeanour throughout this conversation was in my experience extraordinary. She was direct to the point of being unguarded; no doubt she had heard it all before, but she gave no hint of calculating what to say. She was practised at tormenting the British about colonial rule, yet able to talk as a woman of the world. She gave no sign of trading on her political power. Manners aside, her courtesy was her frankness.

John Maddox

Agricultural research

International centres under stress

Washington

THE Consultative Group on International Agricultural Research (CGIAR) meets in Washington this week to decide how the 13 research centres under its control are to respond to continued financial uncertainty. Exchange rate losses caused by the increased value of the dollar, and the growing tendency of donors to support specific programmes judged to bring local benefits rather than backing core research, have meant that the heady expansion of the 1970s has been all but forgotten.

The centres had a total nominal budget last year of \$180 million, but the failure of some donors to meet in full their commitments to the centres has, for several years running, left programmes high and dry. For 1985, the CGIAR technical advisory committee is requesting a total budget of between \$187 million and \$199 million, an increase of 7–14 per cent on the current year, but actual reductions in 1985 are not impossible. The traditional supporters of CGIAR — of which the United States is the largest — are under internal pressure to restrict multilateral aid in favour of support for bilateral projects, whereas the newer donors have not yet been able to make a substantial impact. The World Bank remains the donor of last resort, paying the bills that others have failed to meet.

The Rockefeller Foundation, which founded the first of the agricultural research centres (for breeding wheat, in Mexico) and the Ford Foundation, a substantial sponsor from its early days, have been reducing their contributions to the centres in recent years. Rockefeller is turning instead to centres outside the CGIAR system and is to announce a major initiative in plant cellular and molecular biology before the end of the year, probably based in Mexico. The budget will be in the region of \$5 million a year, but already some are asking whether the Rockefeller Foundation will be able to recruit to Mexico enough high-calibre scientists to justify this outlay.

Despite the financial uncertainty, CGIAR appears confident that most of the centres are still doing a good job. But there is frustration over the plight of some African centres, which have to work with often under-developed national programmes. Local interests seek to direct research efforts towards strictly local problems, an approach which CGIAR feels to be unproductive in the long term. The centres which have historically been the most effective seem to be those with a strictly defined mandate, whereas attempts at some centres to work on a number of different local problems are held to have been less productive.

The International Centre for Agricultural Research in Dry Areas, in Syria, and

the International Livestock Centre for Africa, in Ethiopia, are likely to come under particular scrutiny this week, and there may be attempts to tighten up their programmes. Particular attention will also be paid to the West Africa Rice Development Association (WARDA) in Liberia, which has been under heavy criticism. The future of WARDA within the CGIAR system appears still to be open to doubt, despite some attempts at reform by the WARDA management.

CGIAR has at various times been criticized for advancing the careers of scientists

rather than the fortunes of the developing countries it is intended to benefit. The criticism is apparently taken seriously, to judge from the number of introspective studies by CGIAR now in progress. Should its centres, for example, try to stand in place of national agricultural development programmes where these are seen to be inadequate? There was some agreement in preliminary discussions last week that centres in different parts of the world should be ready to adapt their strategies to local circumstances despite the dangers. There was also an agreement to adopt a plan to foster cooperation between the various institutes, including a joint training programme in farming systems research.

Tim Beardsley

Early success a problem for CGIAR

Washington

THE international research centres supported by CGIAR stem from a crop improvement programme undertaken in the 1940s by the Mexican government and the Rockefeller Foundation. So successful was the project that in 1959 Rockefeller joined forces with the Ford Foundation to establish the first international agricultural research centre, the International Rice Research Centre in the Philippines. In 1966 the two foundations sponsored the second centre, Centro Internacional de Mejoramiento de Maíz y Trigo (CIMMYT) in Mexico, with two more centres following the next year.

By the late 1960s Rockefeller and Ford were each contributing \$3 million annually to the centres, and it became clear they could support no further expansion. In 1971 CGIAR was created at the suggestion of the World Bank to coordinate finances of the centres, which now number 13 in all.

CGIAR, which has a full-time secretariat provided by the World Bank in Washington, remains a completely informal organization with no constitution or charter: its decisions are reached only by consensus among its members.

Funding has changed drastically over the past decade. The US Agency for International Development is now the largest contributor (\$44.5 million in 1983), followed by the World Bank (\$19 million). The International Development Bank contributed \$8 million. The Rockefeller and Ford Foundations have both decreased their contributions recently together accounting for less than \$2 million last year.

But the difficulty for CGIAR now seems to be in living up to the early successes of the first institutes: by the late 1970s Mexican wheat was grown on 29 million hectares of land worldwide, and improved rice strains on 25 million hectares.

Confusion about Chinese names

SIR — Richard J. Wang's note "Xiaoping first?" (308, 768; 1984) only scratched the surface of the issue of Chinese family names in romanization. In the five articles detailing results of the French-Chinese study of the North Himalaya-Tibet area (308, 17-36; 1984), only the second has authors' names correctly abbreviated in the table of contents. Admittedly, it is difficult for the uninitiated to know (or even make an educated guess) at which is the family name.

Confusion begins because the Chinese custom in Chinese is to put family name first, the opposite of the European custom. Added confusion comes because in romanization some Chinese westernize name order (family name last) while others do not. Further, some Chinese hyphenate the *given* name because it is two-character (confusing at first because Europeans sometimes take a hyphenated *family* name), while others (particularly in mainland China) fuse the romanization into one "word". Still others make three separate words for their name, so that the given name would be two words, always to be used together. This last practice is the most confusing since there is no cue to guess the family name; in the other methods, once realized, the hyphen, or the length of the word, allows the given, and thus the family, name to be identified. Even if one is familiar with the common Chinese family names, there are several distinct, widely-used, romanization systems (so Xu = Hsu = Shyu). Further, while pinyin is the sole romanization taught in mainland China, many Chinese elsewhere are not taught any particular system at all, so they sometimes show noticeable creativity. Knowing common last names in one system certainly helps, but not all the time.

The issue raised by all this confusion, particularly in the professional literature, is much more than that of slighting persons or cultures. It can and has already created a mess in indices. For example, to look up articles by Li Tindong in an index or abstracting service, does one look up L. Tindong, as given in that *Nature* table of contents and index. Or is it T. Li? I do not think it would happen, but if an editor insisted on consistency, it could also become T.D. Li, or T.-d. Li, or T.-D. Li. What is one to do? Even the thought of tediously searching each alternative is tiring, not to mention expensive if done through computer hook-up.

As an international journal, *Nature* should not be making these mistakes. Even after Mr Wang's letter I found an article by Zhang Yun (309, 547; 1984) listed in the table of contents and the mid-year index (310, 26 July 84) as Yun, Z. Poor Professor Zhang! Filed under first name. Ignorance could be claimed legitimately by my next-door neighbour, but by *Nature*? Clear, fair instructions to the authors, and clear, fair

editorial rules need to be established to handle these problems. Tell authors to circle family names, or, to indicate that last name, with or without hyphen, will be assumed familial unless otherwise indicated. Then give an example. Errors could be picked up, such as where R. Xu (in the first of the five articles mentioned) inverted his name apparently only because it is last in the list, even though it appears *Nature's* policy not to invert name order because of placement in a list of authorship. Consultation with librarians at an institute for Asian studies might help. After all, *Nature* does not abbreviate L.M. Van Valen as L.M.V. Valen (table of contents 5 January 1984).

I also suggest that indices should include the full romanized Chinese name. There are strong if not compelling reasons to support it. First is the lack of diversity in Chinese family names. Anyone familiar with Chinese names knows how widespread are a small number of family names such as Wang, Chen, Li, Zhou and so on. Indeed, in romanization the situation is worse than in Chinese because homophones (same sound and tone, different character) are so common. In addition, widely-used romanizations do not distinguish total differences, causing further redundancy. The only mitigating factor is

that use of different romanization schemes adds some variability. Chinese given names are quite varied, but all the points on romanization apply here as well. The habit of complete fusing of the given name further reduces variability when the given name is initialized. So the combination of initialling and the commonness of most family names must lead to immense redundancy.

Finally, Chinese names are short. Most are three characters — one familial, two for the given name — a few such as Zhang Yun are two, though a few others are four — for each name. Thus, one would be hard-pressed to find a romanized Chinese name over 15 letters. This is not true for names in many other languages, for example N.C. Vamvakopoulos (table of contents, 5 January 1984). *Nature* has recognized this since Chinese names are given in full at the top of all articles. The policy needs to be extended, perhaps not to the table of contents (so people know the family name!), but definitely to indexes.

With the increasingly large numbers of Chinese names coming into the western scientific literature, there are wide ramifications for information retrieval, not to mention human dignity.

Student fees in Britain

SIR — When a nation is under financial strain, economies are necessary even in an important sector such as scientific research, which in the long run is one of the best investments. One could go further, admitting that financial restrictions, to some extent, may even be beneficial to research, in that they stimulate competition, force a better selection of people and projects and favour a more rational utilization of equipment and resources.

There is one measure, however, to which I would like to call your readers' attention, namely, the higher fees imposed on university students who are not resident in the United Kingdom. Apart from any question of reciprocity (I do not think that British students are requested to pay higher fees in any foreign university), I think that such a rule will ultimately damage British science. I know a case, by no means unique, of a British subject, not resident in the United Kingdom, who, having graduated *cum laude* abroad, wanted to study for a PhD in Britain. She would have been accepted by two leading university departments but at a cost of several thousand pounds. As a result, she accepted a research assistantship leading to a PhD, with an adequate salary, in a department of excellent reputation in another country in the European Community.

This is only one example of how foreign

students and graduates are actually discouraged from coming to Britain. Gifted students at least, especially at postgraduate level, should be attracted, even at the cost of some money. First of all, graduate students do productive work, which would be very cheap indeed if the nation has not borne the cost of their previous support and education. Secondly, when returning home these people will take away with them for life the memory of the country and of the institutions in which they were trained. This will result in the arrival of other young people and in the selling of equipment and may have even greater political implications. Last but not least, many of the best will stay. In this context, there is no need to mention what the United States has gained by recruiting foreign scholars and scientists, often in their youth.

I hope this will not be considered as an undue intrusion into the affairs of a country where I often was and am currently a guest. Indeed, for the gratitude I have for what I learnt and received in your country I felt a moral obligation to express a disinterested opinion on what seems to me a very serious matter.

Civil aviation

SIR — Your leading article on 6 September, p.1 ("Poor show for aviation industry") complains that "civil air transport is not as accessible or cheap as it should be". Perhaps the judgement would be fairer had the article ended "as I would like it to be". The author has clearly not grasped the complexity of an airline operation. The technology necessary to take people around the world near or above the speed of sound costs money, and to do so safely requires one of the most intricate man-made systems most of us encounter. Add to this the requirement to ensure that flying is a positive experience for the customer and that there is a reasonable profit and to cope with political pressures from many governments.

As a pilot with a major international carrier I would hesitate to comment publicly on the financial wisdom of subcontracting aircraft component manufacture, an area which I recognize as only indirectly related to my area of competence.

Indian science

SIR — I would like to add to the explanations which have been given in your columns of the poor quality of research in Indian universities and institutes. The problem at many Indian universities and institutions is a lack of understanding concerning the philosophy of higher education and a lack of sincerity on the part of the academic faculty and administrative staff. There is also a perversion of the professor-student relationship into what often resembles a master-servant relationship.

Many senior scientists from Indian universities and institutes work hard while in the West but when they return to India depend heavily on technicians and students in their laboratories. Another contributing factor is that scientists plan frequent long trips to the Western institutions. Their time in India is mostly spent on collecting money and making arrangements for their next trip. This situation deprives doctoral students of proper guidance from their professors. Often dissertations are presented to the university by the doctoral students in the absence of their major professor.

The concept of higher education in many Indian universities is misunderstood. Comprehensive solutions are required. Despite a huge cut in government support for scientific research in Europe and the United States during the past few years, the number of publications in a scientific journals is increasing. On the other hand, the Indian Government is spending a much greater percentage of the gross national product on science and technology than in

many other nations. Scientists and administrators in India cannot simply sit in their offices cursing the poverty of the Indian economy. In my opinion, the solution lies in increasing the commitment of all those involved in science.

Scientists' oath?

SIR — Television dramas such as *Threads* and *The Day After* make us painfully aware of the great power that scientific and technical knowledge has for evil as well as good. A crucial question is the extent to which scientists, as individuals and as a profession, accept social and ethical responsibility for their research. I suggest that scientists, on graduation, take an oath or make an understanding that their work be for the benefit, rather than detriment, of mankind. Though such an oath would not legally prevent scientists from working on, for example, new nerve gases and new nuclear warhead systems, it might make a start to the establishment of a code of ethics for the scientific profession and bring this body into line with older institutions such as medicine and the church. Such a scientific Hippocratic oath might influence decisions made by individual scientists and a scientific code of ethics might answer an increasingly more popular groundswell of opinion that scientific "progress" *in toto* is not worth the associated risks to the survival of the human species.

Jobs for biochemists

SIR — Richard Pearson's article "Is all science vocational?" (*Nature* 310, 260; 1984) will no doubt be widely read and quoted. As regards the employment of biochemistry graduates, however, the figures obtained by the Biochemical Society, which has been conducting an annual employment survey for some years, indicate a somewhat less gloomy situation. Thus, in 1983, 12.4 per cent of new graduates were still unemployed at the end of the year with another 6.3 per cent unknown as regards employment. At least 80 per cent are known to have found useful occupation within 6 months of graduating, such as further biochemical training for higher degrees (25.4 per cent), biochemical employment (25.5 per cent), other further studies (9.7 per cent) or non-biochemical employment (9 per cent). In addition, 11.7 per cent went abroad, including overseas students returning home and British students taking jobs. Given the present general difficulties as regards employment

of both graduates and non-graduates, these figures suggest that prospects for biochemistry graduates remain reasonably good and apparently considerably better than for biologists.

H.R.V. ARNSTEIN

7 Warwick Court,
High Holborn,
London WC1R 5DP, UK

RICHARD PEARSON REPLIES:

Professor Arnstein's letter provides valuable information about biochemists and highlights the range of employment they have entered in the past. However when making comparisons *between* subjects for example with biologists, it is important to compare like with like and to use common databases as was done in my article. While the statistics are capable of different interpretations, cross-referencing one source to another can lead to inappropriate comparisons.

Animal antibiotics

SIR — In the article by Stephen Budiansky on the emotive subject both sides of the Atlantic, "Are antibiotics in animal feed a threat to human health?" (*Nature* 4 October, p.407), a few statements cannot pass unchallenged.

For instance, the statement* that "none of the bacteria residing in the gut of farm animals is resistant" is just not true¹. Rather than looking for evidence that animal pathogens constitute the source of R plasmids for human pathogens, as is suggested, evidence already points to the R plasmid-carrying indigenous flora in the animal gut as the main reservoir². This reservoir is being selected continuously by the use of antibiotics for whatever purpose. The present debate, therefore, hinges on whether or not subinhibitory, rather than prophylactic or therapeutic, levels of antibiotics play the major role.

Further, the suggestion that the energy cost to bacteria of carrying R plasmids places them at a disadvantage is not scientifically substantiated. It is now recognized that many plasmids are stable entities of the bacterial cell. Also, antibiotic resistance determinants are sometimes genetically linked on the same plasmid with virulence determinants³ and consequently antibiotics select for both types of determinants.

AIDS casts a longer shadow

The good news is of rapid progress in describing what seems to be a new virus — the bad news, proof of heterosexual transmission and of the mounting prevalence of antibodies.

WHILE no patient has yet been cured of the disease called AIDS (for acquired immune deficiency syndrome), it is proper that there should be full-hearted celebration at what has been done to understand the mechanism of this infection. That is one legitimate response to the appearance of the latest contribution from Dr Robert Gallo, at the National Cancer Institute, and his associates there and elsewhere, in France as well as in the United States (see page 166, this issue). The latest development is that Gallo has been able to clone DNA copies of the RNA genome of the virus, called HTLV-III (for human T-cell leukaemia virus), which was identified as the causative agent of AIDS only a few months ago. Presumably it is now a matter of weeks, not months, before the full nucleotide sequence of the 10,000 or so bases in the genome is known. Quite soon, it should also be known whether the vaccines against AIDS will be effective.

So quick has been the succession of events in this saga that it is easy to forget that the disease was first recognized only as recently as 1981. Inevitably, hindsight showed that the disease was not entirely novel — people had been dying from it for at least a couple of years. The chilling feature of AIDS was, and remains, the high mortality among those affected. In advanced societies, there is still no basis on which to deny that those frankly infected will in due course die, usually of some other infection or from Kaposi's sarcoma. That the disease, for the time being, is largely confined to a few groups of people (male homosexuals, those who inject themselves with narcotics and those dependent on blood transfusions, haemophiliacs especially) does not make the social problem less serious or even allow those not in one of the groups at risk to congratulate themselves that they will never come to harm. If, as is probable, HTLV-III is a virus to which the populations of advanced societies are still naive, it is understandable that it should first infect those to whom transmission is easiest. By the same logic, spread will eventually be more general. AIDS should be everybody's worry.

That is another reason for marvelling at the speed with which so much has been learned about the virus, and at the luck that AIDS did not strike ten years earlier, when it would have been much more difficult to disentangle what is going on. One of the crucial steps in characterizing the disease has been the recognition that an almost

invariable accompaniment of overt AIDS is an altered balance between the T lymphocytes called "helpers" and "suppressors". (There are fewer helpers.) These white blood cells are concerned with the regulation of the immune response in ways that are by no means clear. But ten years ago, even the distinction between helper and suppressor cells had not been established.

For the rest, the development of the present understanding of AIDS, and the description of HTLV-III, has followed the path that would have been expected of classical virology — but at an enormously accelerated pace. Gallo's group was able, in 1981, to hit the ground running because of the experience it had acquired in its investigation of the virus now known as HTLV-I, responsible for the disease called adult T-cell leukaemia, first recognized in south-west Japan but then among Caribbean and some African populations. That also upsets the balance between helper and suppressor cells, so that it is not surprising that Gallo and his associates can now also report that the genetic structures of the two viruses have much in common but are also distinct. If that investigation had not been fresh in their minds, it is hard to think that Gallo's group could have made such rapid progress.

But Gallo has not been the only investigator in the field. Professor Louis Montagnier's group at the Institute Pasteur in Paris was formally the first to announce that AIDS is caused by a distinctive virus, in May 1983. That virus, christened LAV, has now been shown to be indistinguishable from HTLV-III, and is also being produced by an infected cultured cell-line. There is even said to be some tension between the two groups. In August this year, Professor Montagnier wrote (see *Nature* 310, 446) in terms suggesting that he and his associates feared they would be overlooked in all the attention being paid to Gallo's fast-moving high-tech enterprise. That would be absurd as well as unjust, for in spite of what has been learned, so much remains to be learned about the biology of AIDS that everybody's energies will be needed before we are safe.

Mercifully, there is movement even towards that goal. Gallo and his associates have reported (*Science* 226, 447; 1984) the presence of HTLV-III in the saliva of apparently healthy male homosexuals and in that of people suffering from what is

called ARC, or AIDS-related complex (which may or may not be an early form of the disease). They have also recovered HTLV-III from the semen of two AIDS patients (*ibid.*, p.449). Guesses at the method of transmission by male homosexuals are thus confirmed; the bad news is that apparently healthy people can be carriers (and presumably transmitters).

It remains perplexing that so little can at present be made of the prevalence of antibodies against HTLV-III among apparently healthy people. Most AIDS patients carry antibodies against the virus, suggesting that their first response to infection was normal, but that their immune system was eventually overwhelmed. There seems to be abundant evidence (little of it published as yet) that the presence of antibodies is widespread among the groups at risk. Only a proportion of those infected by HTLV-III may succumb to AIDS, but, with the long lapse of time (perhaps four years) between infection and overt disease, it is not yet possible to tell how many of them will develop AIDS. Only prospective studies can serve.

Montagnier and the other members of a Franco-Belgian team have made an indirect and preliminary start on this part of the problem. Working in Zaire (once part of the Belgian Congo), they have traced the origin of the first AIDS cases presenting themselves at hospitals in Belgium in 1981. It now emerges (Brun-Vezinet *et al.*, *Science* 226, 453; 1984) that as much as five per cent of the population of Zaire may carry antibodies. By using sera kept in hospital refrigerators from earlier investigations, it has been possible to date one case of AIDS to 1977. The same team (Piot *et al.* *Lancet* ii, 65; 1984) has found unambiguous evidence of heterosexual transmission — and an annual incidence of AIDS as high as 20 per 100,000.

On the face of things, AIDS is nevertheless a new disease. Its nearly simultaneous appearance in Zaire, Haiti and the United States suggests that HTLV-III itself is a novel virus, presumably derived from something like HTLV-I. But how? And why does infection have a profound effect on only one class of T cells? Why should Kaposi's sarcoma, normally rare, be such a common sequel?

For the time being, these questions are wide open. But we are fortunate that Gallo and Montagnier were so quick off the mark, and that they and others now have the techniques they need. **John Maddox**

Fluid flow

Turbulence splits polymers

from A. Keller and J. A. Odell

EVEN minute quantities of long-chain molecules can dramatically influence the flow properties of liquids to which they are added, an effect that has many practical applications. However, limits are set on the usefulness and range of applications of polymer additives by the fact that the longest polymer chains are more effective but are also most likely to break during flow. Horn and Merrill¹ report on page 140 of this issue that such degradation of long flexible polymers subjected to turbulent flow conditions occurs by breakage at the midpoint of the molecules. Such apparently simple observations of degradation are also providing an insight into the molecular processes underlying many problems in fluid transport.

The countless examples of the use of polymers to modify fluid flow range from thixotropic ('non-drip') paints to engine oil viscosity enhancers. The energy required to pump liquids in turbulent flow can be reduced by up to 70 per cent ('drag-reduction') by the presence of a few parts per million of flexible long-chain molecules²; this has found practical applications in pipelines, heating systems and sewage disposal. Recently polymeric aircraft fuel additives have been developed to prevent fuel from 'misting', thereby dramatically reducing the risk of fire in the event of accident³.

The scientific approach to these effects has mostly been that of formal macroscopic hydrodynamics. Explanations on a molecular level have been proposed but are largely untested. A common hypothesis is that the effects are associated with the stretching out of flexible long-chain molecules in the course of flow. Since this process absorbs energy it could suppress droplet formation in misting, or defuse the nucleation of critical vortices during turbulent flow.

The earliest predecessors of Horn and Merrill's observation of midpoint scission of polymer molecules concern DNA⁴⁻⁶, which is not a highly flexible chain, but a rather rigid worm-like entity. Clearly a rigid rod-like molecule in any flow field will experience the greatest force at its centre, so that midpoint scission can be anticipated. But the more common flexible molecule chains are initially present as a tangle (random coil) and their scission would be expected to occur randomly along the chain. Only if the molecule is first straightened out can it be expected to behave as a rod and break at midpoint.

The systematic achievement of full stretching of chains through flow is by no means trivial, as conventional simple shear flows (such as laminar flow in a capillary or between rotating concentric cylinders)

merely distort the coil but do not straighten the chain. Instead, it is necessary to use special elongational flow systems in which there is a uniformly accelerating flow of very high velocity gradient (strain rate). Our own studies⁷ have shown that at a critical strain rate, which depends upon molecular length, the molecules undergo a sharp transition from the random coil to the fully extended state. At a higher and fixed strain rate, the increased force on the stretched-out molecules ruptures them at midpoint. The strain rate required to produce scission is proportional to the square of the length of the chain. This is predictable from the stresses arising in a stretched-out chain subjected to extensional flow. The deduced rupture strength of the chain is comparable to the strength of a covalent bond in the backbone.

This close correspondence between the fracture behaviour of coiled polymers under these model flow conditions and that of a straight molecule provides strong evidence that the coiled chains have been fully stretched out. Merrill and Horn, having corroborated these results and extended them to laminar flow through constrictions⁸, have now transferred the ideas and methodology to the less well

defined, but perhaps practically more important, condition of turbulent flow.

It has been hypothesized that in turbulent flows elongational flow fields prevail locally in vortices, producing local chain extension⁹. This cannot be observed directly on the microscale within the otherwise inhomogeneous turbulent flow, as could be done in the laminar model flow systems. Yet, as now reported, the unique effect of such flow and extension in the form of midpoint scission is observed⁸. By analogy to the experiments with model flow systems, Horn and Merrill infer that the chains must indeed have been stretched out by the turbulent flow field.

With the behaviour of macromolecules in turbulent flow now becoming accessible to experiment, we have reached a firm starting point for a molecular understanding of the intriguing and important flow-modifying effect of macromolecules and its consequences for fluid transport. □

Molecular neurobiology

And now the sodium channel

from Charles F. Stevens

THE cloning and sequencing of the cDNA of the electric eel's sodium channel, described by M. Noda and seventeen colleagues on page 121 of this issue¹, reaffirms that S. Numa's laboratory at Kyoto University is the preeminent factory for cloning peptides and proteins of importance to neural function. More importantly, it is a key step in revealing the molecular basis of the electrical excitability of neural tissue and muscle.

What is the sodium channel and why is it important to clone and sequence its DNA? Channels — as the proteins responsible for brain electrical activity are called — fall into two nearly mutually exclusive classes: ligand-gated and voltage-gated. The former, when bound to by their ligands (specific neurotransmitter molecules) open to permit ion flux across the neuronal membrane. By contrast voltage-gated channels open and close in response to the voltage difference between the inside and outside of the neuron. The archetypal ligand-gated channel is the acetylcholine receptor (AChR). Numa's laboratory was the first to clone and sequence all four

subunits of AChR, and is now first to clone and sequence an example of a voltage-gated channel. In picking the sodium channel, they chose the membrane protein responsible for the nerve impulse.

Not only do AChR and sodium channels fall into different physiological classes, but they also belong to different structural classes. Whereas the AChR is a pentameric protein composed of structurally similar subunits, the picture of the sodium channel that emerges from the cDNA sequence of Noda *et al.* is of structurally similar domains within a single protein. The sodium channel of the electric eel is thought to consist of a single protein of >200,000 molecular mass. The cDNA sequence of this protein shows it to contain four domains, each of which is 250–300 amino acids in length and about 50 per cent homologous with the other three domains. Each domain has a similar overall structure with 6 identifiable subregions; two of these subregions are hydrophobic and presumably membrane-spanning, two are negatively charged, one has a large net positive charge, and one has no net charge.

The AChR is, cell biologically speaking, well behaved. To guide it through the endoplasmic reticulum during synthesis, it has an amino terminal signal sequence of the standard type for an integral membrane protein of eukaryotes. The sodium channel is more of a maverick in that it lacks an amino terminal signal sequence, as do a few other integral membrane proteins including ion pumps^{2,3}, the red cell chloride channel⁴, rhodopsin⁵ and the enzyme, 3-hydroxy-3-methyl-glutaryl coenzyme A reductase⁶.

Where do we go from here? The first and most important step — one which will not be long in coming — must be to demonstrate that the entity whose sequence Numa's laboratory has deduced can, in fact, function as a sodium channel. This proof of function will come from expression experiments of the sort described by Miledi and Parker⁷: mRNA from the cloned cDNA, obtained either by transcription or hybrid selection, will be injected into frog oocytes, which will make the protein and insert it into their surface membranes. If the protein produced is really a whole sodium channel, it will be detectable by electrophysiological techniques.

Another high-priority experiment will be to obtain cDNA clones of other sodium channels, especially the mammalian one, perhaps through their cross-reactivity with the eel cDNA. One interesting strategy will be to look for mRNAs that code for unusually long strings of glutamates — the eel sodium channel cDNA has nine in a row, starting with residue 942. (This approach may also be a route to other voltage-gated channels and a way to start defining family relationships.) The extension from eel to other species is important both for the comparative information that will result, and because the function of the eel channel is hard to study with modern methods, whereas mammalian channels are better understood and more easily studied.

Some aspects of the structural features of the channel deduced by the Numa group are unattractive. For example, it is known that the coupling between membrane field and channel-gating is achieved through a change in the protein's dipole moment associated with the transition between open and closed forms of the channel. This dipole moment change is unusually large (hundreds of Debyes for the sodium channel as compared with tens for the AChR) and must reflect some unusual structural feature of the protein that places movable charges within the membrane, where they will feel the electric field.

Unfortunately, no such feature is discernible in the structure suggested by Noda *et al.* As with the AChR channel, early efforts will be directed towards exploring alternative structures more in accord with physiological constraints.

Finally, we can look forward to structure/function studies of the channel, by means of site-directed mutagenesis of the cDNA. Numa's laboratory has a report in press in *Nature* using this approach for the AChR channel, and several other laboratories are carrying out similar experiments. The methods developed for the AChR will find quick application once clones for the sodium channel become more widely avail-

able. These are exciting times indeed for those with any interest in how the channels that control neural function operate. □

Charles F. Stevens is in the Section of Molecular Neurobiology, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510, USA.

Some 260 times since March, plasma pulses at the Joint European Torus (JET) in Culham have ended disruptively. The spectacular effect, shown above, is instantaneous melting of the Inconel alloy wall of the vacuum chamber by a beam of electrons stripped from the plasma during the disruption. The beam circles the chamber around half-a-million times in near-vertical magnetic fields, picking up energies of a few tens of MeV, and finally hits the inner wall to dump kilojoules of energy in a few milliseconds. The molten and evaporated metal can 'poison' carbon limiters used to limit the outer radius of the plasma ring in later pulses. The damage may contribute to JET's 'impurity problem', when chromium and nickel ions in the plasma radiate energy in interaction with plasma electrons, and limit the degree to which the plasma can be heated for a given rate of energy input. However, JET has shown a better ability to recover from disruptions — returning to normal performance within two pulses — than other tokamaks that have suffered from the same problem and have sometimes required a matter of days to recover.

Erratum

In Grant H. Thomson's article 'Details of Soviet cosmodrome from space shuttle photographs' (18 October, p.607), the words in italics in the following sentence were omitted: "Buildings and signs of construction activity in an area on the north side of the runway are thought to be preparations for the Soviet 'space plane'."

Active galaxies

Assembling the cloudy jigsaw

from Andrew Lawrence and Martin Ward

SOME galaxies have compact sources of radiation at their nuclei which display violent activity on a variety of timescales. It is difficult to identify a unique birthday for research on these active galactic nuclei (AGN), but there was no doubt that Professor Don Osterbrock of the Lick Observatory, and a distinguished AGN researcher, was 60 in July. At a workshop* held in celebration of that event, there was a feeling of substantial recent progress in three main areas: the understanding of the glowing gas surrounding AGN; the mapping of the overall energy budget of AGN at all emitting wavelengths; and the realization that activity in galactic nuclei is ubiquitous.

AGN are easily recognised by the bright optical emission lines in their spectra, arising from surrounding gas clouds heated by the central source of radiation. To understand the physical condition of the ionized gas, such as its temperature and density, much use is made of the relative intensities of the emission lines. D. Osterbrock reviewed the by now large data base on this topic, much of it gathered by himself and his graduate students at the Lick Observatory. This work has provided the information essential for the construction of models of line emitting regions. Indeed, a 'heavy industry' in AGN theory is that of modelling the shapes and strengths of the emission lines. Predictions from the standard model of a collection of identical optically thick clouds generally match the data well but several pieces of evidence imply the presence of a continuous range of densities and sizes in these clouds. In particular, B. Peterson (Ohio State University) argued from the variability of emission lines in AKN 120 that the clouds are uncomfortably close to the central radiation source and must evaporate, unless some of them are of a very high density. And W. Mathews (University of California, Santa Cruz) argued that symmetric Lyman alpha profiles further imply a substantial population of thin clouds.

Another outstanding problem is that of permitted ion emission, Fe II. This atomic species has an incredibly rich line spectrum in both the optical and the ultraviolet, but the spectrum is hard to model because, in certain parts, the multitude of Fe II lines can blend together to produce a false continuum (H. Netzer, Wise Observatory, Israel). In broad line radio galaxies, where the lines are even broader than usual, this may explain why Fe II was thought to be weak or absent. Since the lines are so broad they are 'washed out' and become part of

an apparently smooth continuum (B. Wills, University of Texas).

The profiles of these broad emission lines, produced by very fast cloud motions, must hold clues to the kinematics and geometry of the cloud regions. Much evidence points to radial motions but optically thick clouds, which would be bright on the side facing the central radiation source and dark on the back, should then lead to very different red and blue emission line wings. Because that is not usually observed, it further implies a mixture of thick and thin clouds. A. Filippenko (California Institute of Technology) and W. Ku (Columbia Astrophysics Laboratory) showed that lines from different atomic species often have very different profiles, again implying a physical stratification of the cloud regions. However, an interesting new idea regarding the line symmetry problem invoked the possibility of parabolic orbits, so that clouds are moving both out and in (J. Kwan, University of Massachusetts). And T. Kallman (Goddard Space Flight Center) suggested that in presence of a gaseous intercloud medium, scattering of ionizing photons could illuminate the back of clouds, making them bright on both sides. Finally, the radial motions need not be spherically symmetrical. M. de Robertis (Lick Observatory) presented a new model of a bi-conical expanding cloud region; viewed from different angles this could produce the various line profiles observed.

Energy budget

The second area of progress has been in understanding the continuum radiation from the central object itself. What is observed through a specific frequency window is often a mixture of components, such as synchrotron radiation, heated dust grain emission, atmospheres of hot young stars, and possibly thermal emission from a hot accretion disc surrounding a black hole. The sorting out of these different components, and their relative contributions to the total energy output of AGN, is now a major thrust of observational effort.

M. Malkan (Steward Observatory) argued for a 'thermal excess' in the blue over an underlying power law (the so-called 'blue bump') that may represent the radiation from an accretion disc. Others believe that this may be explained away by substantial Fe II and Balmer continuum emission from the surrounding clouds. M. Elvis (Smithsonian Center for Astrophysics) presented new soft X-ray data on optically selected quasars. The usually expected flattish X-ray slope was often not seen — rather, a variety of considerably steeper X-ray slopes were observed. Placed in the context of IR, optical and UV data, it

seems that the soft X rays in these cases may represent the high energy tail of the thermal excess postulated by Malkan. Furthermore a second 'little bump' is often visible on top of the 'big bump'. This presumably is the Fe II and Balmer continuum emission. This seems to resolve some of the controversy about the 'blue bump', in that we must be clear which 'bump' we are discussing.

J. Bechtold (Steward Observatory) and M. Malkan showed that the relative amounts of power-law and thermal components can be quite different in different AGN. Correlations within the properties of the power-law and thermal components, when considered separately, are generally good. M. Ward (Institute of Astronomy, Cambridge), using plots of the total energy output of AGN, emphasized that in many cases much of the energy must emerge at the peak of the thermal component in the extreme ultraviolet region (XUV). Unfortunately, this is currently an unobserved region — we see only the low energy UV head, and the high energy X-ray tail. To understand its true nature we need to observe the XUV body.

The third important area of progress is in recognizing that activity in the nuclei of galaxies is really widespread. As a result of sensitive spectroscopic surveys by W. Keel (Kitt Peak National Observatory) and T. Heckman (University of Maryland) it seems that 30 per cent of spiral galaxies have optical emission lines. This ionized gas cannot be produced by the radiation field of a population of normal semi-evolved stars. The required ionizing radiation could come from a small number of young, extremely hot massive stars, or be a dilute version of the power-law continuum radiation seen in quasars, or be shocked gas resulting from gas cloud collisions. Keel presented fresh evidence that these weakly active galaxies tend to have close companions somewhat more often than non-active galaxies — but the situation is confused. The presence of close companions seems to be a statistically significant factor, but is very far from being either a necessary or a sufficient condition for activity.

Much debate centred around the nature of the so-called Type II Seyferts. These are similar to the classical quasar-like AGN (most of which are classified as Type I Seyferts), but without the very broad emission lines or strong optical-UV-X-ray continuum. What remains are the strong narrow emission lines, and copious IR emission, almost certainly from heated dust grains. These are both features believed to come from the very large surrounding low density region. It is as if Type II Seyferts were Type I Seyferts with the energetic middle bits missing. D. Osterbrock and collaborators have long emphasized the existence of 'intermediate' types, with relatively weak broad lines and continuum, and evidence for a continuity of properties in several frequency regions was presented by A. Lawrence (Royal

*16-27 July 1984, Santa Cruz, California.

Greenwich Observatory) and R. Cohen (University of California, San Diego). However, A. Wilson (University of Maryland) argued that there exists a distinct difference in radio properties between Type I and Type II Seyferts. Some Type II Seyferts are really Type I Seyferts obscured by gas and dust; others may be 'switched off' Type I Seyferts — when the central radiation source switches off, the compact high density, high velocity cloud region will soon also disappear, but the very large low density regions may remain glowing for from hundreds to a few thousand years. Evidence for AGN changing their type on a timescale of decades was shown by Lawrence, Cohen and N. Bochkarev (University of California, Berkeley).

At least some of the classical Type II Seyferts may be quite different. J. Miller (Lick Observatory) reported that the Seyfert Type II NGC1068 has a highly polarised non-stellar continuum which extends through to the UV and soft X rays.

The emission lines are less polarised and those preferentially emitted from low density gas (the so-called 'forbidden lines') are polarised at a different angle from the permitted lines. This suggests that the central high density gas is present after all but for some reason is not moving at the great velocities characteristic of Type I Seyferts. G. Ferland (University of Kentucky) presented UV data for several Type II Seyferts which further showed that they do have a non-stellar continuum but that it is very weak.

Sitting through the workshop, one had the feeling of assembling a giant jigsaw puzzle. We have at least the majority of the pieces and have completed the edges. Now we must take a deep breath before attempting to make sense of the picture in the middle. □

Neurobiology

Memory and molecular turnover

from Francis Crick

RECENT spectacular advances in molecular biology will, before long, begin to make a massive impact on certain key problems in neurobiology. A synapse is a complex piece of molecular apparatus, but there is now no technical reason why all its components — not merely the major ones — should not be isolated, sequenced and characterized. We can expect to have a detailed knowledge of the many ion channels, receptors and so forth, almost at will, for any type of neuron in any species. All this, together with techniques such as patch-clamping, should put the behaviour of synapses on a solid foundation and in the process tell us something about the molecular basis of memory. However, in spite of recent advances in understanding memory, in both *Aplysia* and long-term potentiation in the hippocampus, one aspect is often overlooked.

The time span of human memory (without obvious rehearsal) is often a matter of years, sometimes even tens of years. Yet it is believed that almost all the molecules in our bodies, with the exception of DNA, turn over in a matter of days, weeks or at the most a few months. How then is memory stored in the brain so that its trace is relatively immune to molecular turnover?

Several possible solutions of the problem suggest themselves. For example, memory might be coded in alterations to particular stretches of chromosomal DNA. Much current thinking assumes that memory is stored, at least in part, in the 'strength' of (many) individual synapses, so this would imply that in any neuron there is a special piece of DNA for each of its synapses, generated perhaps by similar means to

those used in cells of the immune system. This seems unlikely. A related alternative is that there is a special *local* piece of DNA (or perhaps RNA) for each relevant synapse. For example, it is conceivable that each spine apparatus has its own piece of nucleic acid which is modified when the system needs to alter the strength of that synapse. This idea also does not seem very likely but might be worth bearing in mind, since each mitochondrion has its own piece of DNA.

Another alternative is that each synapse has at least one macromolecule which is relatively immune from molecular turnover. Again this does not seem very probable but such a molecule could be looked for by appropriate pulse-chase experiments during development.

Since none of these alternatives seems especially attractive, one is more inclined to suggest models that are cooperative in nature. That is, the molecules in the synapse interact in such a way that they can be replaced with new material, one at a time, without altering the overall state of the structure. It is easily possible to conceive many such hypothetical models. It occurred to me to think of the simplest.

Consider, for example, a protein molecule that is an essential part of a synapse and can exist in two states: active and inactive. Suppose the molecule forms a dimer, probably with a two-fold rotation axis, that can be modified chemically by, for example, the attachment of a phosphate group. Let us assume that when both monomers are modified the protein is in the active state, symbolized by (+, +) and that when both are unmodified the dimer is in-

active, symbolized as (-, -). In addition, let us assume the existence of an enzyme that will add a phosphate group (or whatever the modifier is) to one monomer if the other monomer of the dimer is already modified but not otherwise. That is, it will turn a (+, -) into a (+, +) but will not touch a (-, -).

Assume, furthermore, that the mechanism for altering the synaptic strength can phosphorylate the dimer when more parts of the synapse are to be made active and can dephosphorylate it when activity is to be reduced. That is, the mechanism can turn a (+, +) into a (-, -), or vice versa.

Finally I assume that individual monomers of a single dimer can be replaced one at a time by the mechanisms responsible for molecular turnover and that these new monomers are initially unmodified.

This system will have the property that whether the dimer is in the active (+, +) state or in the inactive (-, -) state, the substitution of a single new unmodified monomer for either of its two components will leave it in the same state. That is, molecular turnover will turn a (+, +) into a (-, +) but the hypothetical enzyme will convert this back to (+, +). The (-, -) state will of course remain (-, -) during metabolic turnover. This mechanism is obviously modelled on known mechanisms for the maintenance methylation of DNA, as reviewed by Razin, A. and Friedman, J. in *Progress in Nucleic Acid Research and Molecular Biology*, Vol. 25 (ed. Cohn, W.E.) 33 (Academic Press, 1981).

It is possible to imagine more complicated models of this general type. The macromolecule could be a trimer or a tetramer; there might be more than one modifiable site per monomer; rather than phosphorylation, the modification might be dephosphorylation, or methylation, glycosylation and so forth.

There are a number of subsidiary conditions. The macromolecule should be anchored to a particular synapse and not be free, in its mature form, to migrate from one synapse to another. This might suggest it would probably be a membrane protein and perhaps form part of a larger aggregate of some form. The supply of newly synthesized monomers should be immune to the modification (or demodification) process. The old monomers, due to be discarded by molecular turnover, should not interfere with the above processes.

Since the proposed mechanism is not implausible it would be sensible to look carefully for modifications to synaptic proteins and for the enzymes which modify and demodify them, in case one of these enzymes should have the peculiar characteristics described above. If such an enzyme were found it might prove to be a pointer to the seat of long-term memory. □

Atmospheric carbon dioxide

Predicting plant productivity and water resources

from T.M.L. Wigley, K.R. Briffa and P.D. Jones

PLANTS love carbon dioxide. At elevated atmospheric CO_2 concentrations photosynthesis (and hence productivity) is enhanced, plants transpire less and make more efficient use of soil moisture reserves. In assessing the agricultural and hydrological consequences of anthropogenic CO_2 increases, we must, therefore, consider both CO_2 -induced changes in climate and the direct effects of increased CO_2 on plant physiology. The latter could be as important as the former, and may well be more easily predicted. Two recent papers have addressed different facets of this issue. In one, LaMarche *et al.*¹ suggest that recent increases in the growth of some high-altitude trees might be attributable to the direct effects of increased atmospheric CO_2 . In the other, Idso and Brazel² examine the effect of a CO_2 -induced increase in the efficiency of water use by plants on river basin evapotranspiration and river flow. Because Idso and Brazel assume that controlled-environment experimental results can be transposed to the real world, it is particularly important to demonstrate the validity of their assumption.

Before describing the work of LaMarche *et al.*, we can estimate the magnitude of increased tree growth that might be expected to occur under laboratory conditions due to a 25 per cent increase in CO_2 concentration, the change that has occurred since the mid-nineteenth century. To do this we use the well-known relationship between net primary productivity (NPP, roughly equivalent to tree ring width times mean density in this case) and CO_2 concentration (C): $\text{NPP} = \text{NPP}_0 [1 + \beta \ln(C/C_0)]$. β in this equation must be determined empirically and its value is still uncertain. Using $\beta = 0.3\text{--}0.7$ (see ref. 3) the implied change in NPP should be 7–16 per cent. This is a sufficiently small change that it would be exceedingly difficult to detect, given the natural variability of plant growth.

In fact, β may be even less. The values quoted are based largely on small-scale experiments which, as noted above, may not be applicable to the real world. A more relevant value can be estimated from carbon-cycle modelling studies but modelling uncertainties are such that a β value as small as zero is not ruled out. Since carbon-cycle models are our main tool for predicting future CO_2 levels, and since these predictions depend on the chosen value of β , it is clearly of importance to detect enhanced photosynthesis in the unmanaged biosphere in order to demonstrate that β is significantly greater than

zero.

In their field study, LaMarche *et al.* examined variations in bristlecone pine ring widths at two high-altitude sites in the White Mountains of eastern California, approximately 370 km east of San Francisco, and in limber pine ring widths at a site high up on Mount Jefferson, Nevada, about 180 km northeast of the other sites. At all three sites LaMarche *et al.* found an increase in tree growth since the early nineteenth century and particularly over the last 20 years. For the two Californian sites, where the tree ring data extend back many centuries⁴, the changes are unprecedented. Furthermore, the increases in ring width shown by LaMarche *et al.* exceed 70 per cent over the past 150 years, much greater than any anticipated changes (unless there has been a correspondingly large reduction in wood density). This clearly points towards some unusual cause, and CO_2 is implicated because it too has shown an unprecedented increase over the last century. However, if CO_2 were the cause we would expect the effects to be widespread and relatively small. Other bristlecone pine and limber pine chronologies exist near to the sites studied⁴, but not all of these show the same upward growth trends. Further research is required to explain this site specificity and the apparently large amplification of the CO_2 effect. Could, for example, an amplified effect occur specifically at locations near the tree line if there were a CO_2 -induced reduction in the threshold temperature for photosynthesis?

Alternatively, are these changes due to climatic change? LaMarche *et al.* consider only temperature and precipitation changes (neither show any recent trends), and their analysis is inconclusive because the climate–tree growth relationship is not well-defined. To complicate the issue further, climate may be indirectly involved; for example, since 1960 the regional westerly wind component has increased in a way that, at least superficially, matches the tree growth trends. Could changes in nutrient input due to pollutant transport from the industrial and agricultural areas around San Francisco be the link? While intriguing, the data of LaMarche *et al.* are not yet enough to support any claim that the growth changes are related to CO_2 increases, and the authors are justifiably cautious in their conclusions.

Idso and Brazel are not concerned with small past changes, but with the much larger increases in CO_2 that might occur in the future. They consider the case where the CO_2 level is double the pre-industrial

level — a value expected to occur around the mid-twenty-first century — and examine the effects of CO_2 -induced changes in water use by plants in line with the NPP relationship given above.

Higher CO_2 levels reduce evapotranspiration by causing the stomata to close. When evapotranspiration is reduced, more precipitation will be available for runoff, so reducing the normal depletion of soil moisture reserves during the growing season. Thus, whereas the potential effects of any reduction in precipitation caused by increased CO_2 concentration could be offset via the direct effects of CO_2 on evapotranspiration, the effects of an increase in precipitation might be enhanced. To study the relative effects of these two processes requires both a knowledge of the future change in climate and a detailed model of the vegetation. Idso and Brazel use a simple water balance calculation, coupled with the climate scenarios assumed in an earlier study⁵, to assess the sensitivity of runoff to both effects. Their results indicate that direct CO_2 effects could more than offset influence of even such large changes in climate as a 10 per cent drop in precipitation coupled with a 2°C rise in temperature. In a much more complex analysis, Aston⁶ has reached a similar conclusion.

The changes in agricultural and hydrological resources predicted by these studies will have to be considered carefully in future planning. Both, however, are exploratory, and depend on a number of simplifying assumptions. Idso and Brazel, for example, take no account of the seasonal distribution of precipitation and evapotranspiration. If most of the runoff were associated with winter precipitation (for example, through snow melt) then a reduction in drainage basin evaporative losses during the growing season could have only a minor effect on annual runoff. Even during the growing season, the reduction in evapotranspiration may be offset by an increase in leaf (transpiring surface) area, a factor considered in neither study. Calculations by Goudriaan *et al.*⁷ using a very detailed plant physiological model, show that increased leaf area could largely compensate for reduced transpiration rate per unit leaf area. However, as Aston points out, this would not operate in tropical regions where C-4 plants often dominate.

These are all exceedingly complex issues. Future changes in atmospheric CO_2 level

are expected to far exceed any changes that have occurred to date. Even in the absence of marked changes in climate, atmospheric CO₂ may have dramatic effects on agriculture and water resources. To support rational planning for this eventuality, we require more studies like those discussed here to increase our quantitative knowledge of the influences of CO₂. But

much more groundwork is required before we can make predictions that have practical value. We may have only a decade or so in which to make the step from speculation to application. □

Palaeoecology

Hampstead Heath clue to historical decline of elms

from Peter D. Moore

LIKE human history, palaeoecology can be a frustrating occupation. How can one hope to construct a satisfactory, scientific explanation for an event which appears to have taken place on only one occasion in the fossil record? The whole basis of uniformitarianism begins to totter at this point. On the other hand, such events can fuel endless speculation, the pleasures of which tend to offset the frustrations. One of these has become a recurrent theme in the Quaternary palaeoecology of Europe: the decline in elm pollen which occurred quite abruptly across much of northern Europe, some five thousand years ago. It was this theme which reared its enigmatic canopy over a recent conference of botanists and archaeologists at Oxford*.

In the past few years, the debate has lost something of its vigour simply because no new evidence has come to light. It has been established that the collapse of the elm pollen in the stratigraphic record is widespread, relatively synchronous (within a 300–400 year period over a very large area, as indicated by dates which themselves, however, have broad inherent error margins). There are some isolated locations where the elm decline is less marked, but even in the extreme north of Europe, far beyond the limits of elm, it is often possible to detect a drop in the elm pollen that had been transported over considerable distances.

One of the major controversies has centred around the coincidence of the first clear indications of agricultural activity by Neolithic peoples with the elm decline, which has led to interesting speculations about primitive forestry practice and contemporaneous human population levels. Models advanced to explain the elm decline have evolved over the decades in a punctuated manner, each quantum leap being dependent on the acquisition of some new item of circumstantial evidence which permits further elaboration, or even a complete restructuring of the theory. Climatic change gave way to soil deterioration, which was overthrown by the radical

proposition that man stripped the elm trees of their branches in order to feed stockaded domestic herbivores.

After a period of equilibrium, if not stagnation, the topic seems set to make another leap, and the evidence is coming from a number of directions. In the first place, it has become apparent that agricultural activity in Britain was widespread prior to the elm decline. This fact was demonstrated at the Conference by the data of J. Innes and I.G. Simmons (University of Durham). Their work on the North York Moors clearly shows that there were episodes of forest clearance during what are presumed to be Mesolithic times. Evidently the advent of agricultural ideas and practices in northern Europe was not a sudden, revolutionary event. In a recent analysis of the first occurrence of cereal-type pollen grains, Edwards and Hiron (*J. archaeol. Sci.* 11, 71; 1984) showed a wide geographical scatter of records in Britain prior to the elm decline. Whether these derive from Mesolithic or Neolithic cultural activity is impossible to say and may in any case be a rather meaningless question. What is important is that the earliest agriculture was underway before the elm decline, which was therefore not the outcome of any large-scale invasion of innovative, agricultural techniques.

A similar conclusion has been drawn by J. Turner (University of Durham) who displayed pollen diagrams based on contiguous 1 mm microtome slices of a frozen peat core from the North Pennines. These showed a progressive decline in elm, evidently related to the succession of clearance events which had been taking place in the region over a period of several hundred, possibly a thousand years. Since the elm decline is also accompanied by falling levels of lime (*Tilia*) and ash (*Fraxinus*), Turner is inclined to the idea that the cumulative effect of centuries of Mesolithic wear and tear on the vegetation has resulted in the depletion of soil nutrients, leading to a decline in all three species. She has also proposed, on the basis of the pore numbers in the fossil elm pollen, that the elm in question in the area was not the wych elm, *Ulmus glabra*, as

expected, but was more probably *U. minor* (see Stockmarr, *Danm. Geol. Unders.* IV R 4, No. 11; 1970). Since this taxon is climatically more sensitive than the wych elm, the suggestion could cause the entire debate to return to its starting point of some forty years ago.

It was at this point, however, that fuel was added to the fire from an unexpected quarter. M. Girling (English Heritage) announced the discovery of wing cases from an interesting beetle in sediments just 10 cm below the elm decline at a site on Hampstead Heath, London. The beetle she identifies as *Scolytus scolytus*, the carrier of the fungus, *Ceratocystis ulmi*, that is the cause of Dutch elm disease.

The proposal that the decline of elm 5,000 years ago was the product of a disease is not in itself new (see W.A. Watts, *Proc. Linn. Soc. Lond.* 172, 33; 1960). It has become increasingly attractive, even compulsive, as we have observed the recent effects of Dutch elm disease on elm populations. But healthy speculation feeds upon circumstantial evidence and here, at last, we seem to have it. If the beetle vector was here 5,000 years ago, perhaps the disease was too. Was the sudden onset of the disease the result of early forestry? And how do we explain the concurrent decline in some other trees, such as lime? The answers are still not clear, and can never be entirely testable, but the new evidence will provide the necessary momentum for renewed vigour in an old debate. □

100 years ago

NATURAL SCIENCE IN SCHOOLS

HOWEVER fully it may be admitted by the few that it is important, nay essential, that all members of the community, whatever their station or occupation should during their school career receive some instruction in the elements of natural science, the general public have not as yet had brought home to them with sufficient clearness that, just as a knowledge of foreign languages is essential to all who are brought into intercourse with foreigners, so in like manner is a correct knowledge of the elements of natural science of direct practical value to all in their daily intercourse with Nature, apart from the pleasure which such knowledge affords. In fact, from a purely utilitarian standpoint, the advantages to be derived from even most elementary acquaintance with what may be termed the science of daily life are so manifold that, if once understood by the public, the claims of science to a place in the ordinary school course must meet with universal recognition. To quote Huxley: "Knowledge of Nature is the guide of practical conduct. Any one who tries to live without attention to the laws of Nature will live but a very short time."

Psychiatry

Complexities of cause and effect in anorexia nervosa

from Nicholas Mrosovsky

EXTREMES in body weight such as gross obesity or the emaciation of anorexia nervosa are accompanied by numerous physiological, behavioural and psychological changes. These disturbances are so interwoven that it is difficult to disentangle the primary factors. Classic studies by Sims and Horton¹ have demonstrated that, simply by overeating, volunteers of normal weight can obtain obese-type endocrinological profiles; when the period of overeating ends, body weight returns to normal and the endocrinological symptoms subside. Such findings suggest that, at least in some types of obesity, these particular symptoms are a consequence of being fat rather than instrumental in initiating overweight. This approach has now been applied to the problem of anorexia nervosa by Fichter and Pirke and their co-workers at the University of Munich and the Max-Planck-Institut für Psychiatrie².

The well-known Minnesota studies of Keys *et al.*³ have already shown that starvation induces a number of features that are common in anorexia nervosa; obsession with food and rituals surrounding meals are obvious examples. However, these observations were made on young men, while Fichter and Pirke selected subjects and measures with anorexia nervosa specifically in mind. Young women in their early twenties and close to 'ideal' weight volunteered to go without food, other than certain minerals and vitamins, for three weeks. A number of changes, reminiscent of anorexia nervosa, occurred during the fast, including elevated blood cortisol, abnormal dexamethasone suppression tests, blunted response to thyrotropin-releasing hormone, lower levels of luteinizing hormone (LH) and regression of the 24 h LH secretory profile to the infantile pattern. The LH changes were not consistent. However, the average weight loss of 8 Kg was small compared with percentage reductions from ideal body weight commonly observed in anorexia nervosa. In general, apart from some less clear data with growth hormone, "the results support the hypothesis that the endocrine disturbances reported in anorexia nervosa are not primary but rather the consequences of reduced food intake or loss of body weight"².

While the results of the Fichter and Pirke study are consistent with the view that many physiological symptoms of anorexia nervosa are secondary to weight loss, there remain counter-arguments. The relationships of endocrine function to body weight in anorexics are by no means simple. For instance, weight recovery does not always

lead to normalization of LH levels⁵ and changes in the metabolism of brain nor-epinephrine sometimes last for months after nutritional rehabilitation⁵.

An abiding question about such counter-arguments is what do we mean by 'recovery'? Usually this is defined in terms of attaining a weight near to the ideal level for the age and height of the patient. This is far from satisfactory since it is not uncommon for anorexics to have been above average weight prior to the disease. Persistence of endocrinological abnormality in an individual might reflect a failure to recover to an appropriate weight for that individual. What is needed are indices of recovery other than average population weights from the Metropolitan Life Insurance tables. Even when the patient's own pre-morbid weight is used, there is the problem of defining the onset of the disease; moreover, anorexics often have unstable weights. Further studies of the effects of fasting and refeeding on people of stable weight, who do not normally diet, should provide better indices of deviations from an individual's own physiologically-regulated weight level. Without these, the relationship of endocrine function to body weight in anorexic patients may remain obscure.

The idea of a strong biological component in anorexia nervosa has been entertained ever since the disorder was first described. Prospective longitudinal studies, with measurement of many physiological variable are costly and difficult. Given this vacuum, the experimental approach taken by the Munich group provides some of the most important information we have on the topic and may be destined to take its place alongside other classic studies on weight manipulation in normal subjects. Of course, these studies do not preclude predisposing factors or the possibility that a primary abnormality in metabolic regulation may result in weight changes which in turn produce secondary changes¹. Therefore the question of whether there are primary physiological disturbances in anorexia nervosa has not yet been resolved. It would be a fair summary of present knowledge to say that not one of the somatic symptoms has yet been proven to be primary in the disorder, and that a large number of these symptoms are not specific to anorexia nervosa, but can be produced by weight loss alone. □

Nuclear physics

From little bang to Big Bang

from Neil Rowley

AT sufficiently high incident energies, the system formed in a head-on collision of two heavy nuclei will 'explode', showering fragments in all directions. A new generation of particle detectors, which almost completely surround the target in such a collision, makes it possible to detect enough members of the shower to reconstruct some details of the initial event. Two experiments of this kind have recently been completed on the Bevalac at the Lawrence Berkeley Laboratory in California; the results of both hint at the possibility of some exciting new physics.

The first experiment, by H.A. Gustafsson *et al.* (*Phys. Rev. Lett.* **52**, 1590; 1984) employed the 'Plastic Ball' spectrometer to investigate the possibility of observing collective flow of nuclear matter in Ca + Ca and Nb + Nb collisions at 400 MeV per nucleon. The observation of such collective effects would give hope that some very exotic phases of nuclear matter could be created by relativistic

heavy-ion collisions.

In order to explore an equation of state and look for possible phase transitions, a large sample of matter needs to be taken and subjected to controlled variations of temperature and pressure. This is not so easy for nuclear matter since we only possess relatively small samples — the stable nuclei — and we can only vary the ambient conditions by forming hot compressed systems in short-lived nuclear reactions. Here the finite size of the nucleus is an apparent problem since nucleons with a high kinetic energy might rapidly escape from the compound system and thermal equilibrium may never be established.

At low excitation energies, the mean-free-path of a neutron or proton in a heavy nucleus is indeed large (at least when compared with the nuclear radius), though each nucleon is confined by the average field of all the others. Thus one might expect that highly excited nucleons would escape without scattering. The reason for

Fig. 1 High-energy collision of identical nuclei in the centre-of-mass frame. *a*, Non-central collisions. The sections of target and projectile which did not overlap remain as relatively 'cold spectators' moving with their original velocities. The overlapping sections form a 'fireball' whose centre-of-mass is at rest. There may, however, be collective flow in the fireball which decays rapidly by thermal particle emission. The final momentum distribution has the collective momenta superimposed on top of a statistical distribution from the decay. *b*, Head-on collision. All the mass is compressed into the fireball. In the hydrodynamical model this mass is squeezed out in a collective flow at right angles to the original beam direction. The system still decays by statistical emission but with an additional perpendicular component to the momentum. The flow may be very different if the target and projectile have significantly different masses (see text).

the large mean-free-path is, however, rather special. Nucleon-nucleon interactions are inhibited by the Pauli principle which prevents a neutron (proton) from scattering into a state already occupied by another neutron (proton). For very fast collisions many high-energy unoccupied states become accessible, the nucleon-nucleon scattering regains its full vitality and the nucleon mean-free-path becomes very small. At 400 MeV per nucleon the Pauli blocking may essentially be ignored.

It has already been established that in high-energy nucleus-nucleus collisions the emitted charged particles have an energy distribution which is consistent with a system that has fleetingly achieved thermal equilibrium. The observation of equilibrated particle spectra unfortunately tells us nothing about the internal pressure of the system. At the limit of small mean-free-path, however, a system should behave hydro-dynamically and it should be possible to set up local pressure gradients and generate collective flows. The problem is that long before reaching any detector, the hot 'fireball' formed from the overlapping regions of the target and projectile (see Fig. 1) will have 'radiated' away to nothing. The only way of knowing if such hydrodynamical effects exist is to detect as many as possible of the radiated particles, measure their momenta and reconstruct the flows existing before the fireball disintegrated. This was the aim of the experiment Gustafsson *et al.*

A further difficulty in interpreting the data from such experiments is that hydro-dynamics predicts collective flows which depend on whether the collision is head-on

(see Fig. 1*b*) or more peripheral (Fig. 1*a*). The enormous power of a detector like the Plastic Ball lies in the fact that it is actually a large number (815) of electronically coupled detectors covering a solid angle of almost 4π , that is almost completely surrounding the target. By detecting many low-mass charged particles in coincidence with one another, it is possible to have a high degree of confidence that they originated from a single event and to relate qualitatively the particle multiplicity to the size of the fireball.

For identical nuclei the most dramatic event is the head-on collision — giving rise to high multiplicity. Here the hydro-dynamical model predicts that the matter is squeezed out at right angles to the original beam velocity (see Fig. 1*b*). This event is referred to as 'sidesplash' and the direction of flow relative to the beam axis is specified by the flow angle. This should be 90° for a head-on collision. For the Ca + Ca experiment of Gustafsson *et al.* the results are disappointing. For all but the highest multiplicities the particle cross section is peaked at 0° , that is along the axis. This is consistent with a purely statistical decay and gives no evidence for collective flow. Only for the highest multiplicity events is a small deflection, of around 10° , observed.

For the more massive Nb + Nb experiment the results are much more encouraging. A finite flow angle is observed and it increases steadily with increasing multiplicity up to a maximum value of around 30° . This is far short of the expected 90° for a head-on collision but the occurrence of such a direct event is rather infrequent and the flow angle drops rapidly

to zero with decreasing projectile-target overlap. The theoretical analysis of Buchwald *et al.* (*Phys. Rev. Lett.* **52**, 1594; 1984) shows that when these effects and the detector efficiencies are taken into account a maximum average flow angle of about 30° means that collective hydrodynamical flow has been established.

More recently the mass-asymmetric system Ar + Pb has also been studied at the Bevalac in collisions at energies around 800 MeV per nucleon (Renfordt, R.E. *et al.* *Phys. Rev. Lett.* **53**, 763; 1984). Here an interesting twist to the flow-angle behaviour has been observed: for very central collisions (highest multiplicities) the fragment distribution is almost isotropic and there is no discernible flow angle.

Surprisingly, this result is again consistent with the hydrodynamical model which shows that the behaviour is due to the different 'geometry' of the system. In a central collision the Ar nucleus is totally engulfed by the larger Pb target in which it is brought to an abrupt halt. Since the kinetic energy is entirely deposited in the interior of the target this results in an almost isotropic expansion of the composite system. Statistical or 'cascade' models (see Cugnon, J. *et al.* *Phys. Lett.* **109B**, 167; 1982) do not produce such a large stopping power since they cannot describe the vital compressional modes. In these models some remnant of the initial beam velocity survives giving a forward peaking of the fragment distribution — a prediction inconsistent with the results of the second experiment and the Nb + Nb data.

For lower multiplicity events, however, the asymmetric system does exhibit a finite flow angle. The maximum value appears to occur for collisions where the Ar projectile is just eclipsed by the larger Pb target. This configuration now resembles the head-on collision for the mass-symmetric system, since the non-overlapping part of the target may be regarded as a spectator. The result is again elegantly reproduced in the hydro-dynamical picture.

It does therefore seem possible to compress nuclear matter in such experiments. If compressions to around three times normal density can be achieved, then theory predicts the existence of a nuclear phase containing a Bose-condensate of pions. An even more alluring goal (though higher energy beams would be required) is the creation of a fireball in the phase of a quark-gluon plasma. Such experiments are our only possible means of reproducing in the laboratory a state of matter that only existed at the very beginning of the Universe. The creation of such exotic phases may still be far away but the new Bevalac results are an important step in the right direction. □

Molecular evolution

On the origin of the *Alu* family of repeated sequences

from Andrew Leigh Brown

7SL RNA is an example of a eukaryotic RNA species that was identified long before a cellular role could be ascribed to it. Only recently was it established¹ that it forms an essential part of the signal recognition particle — the cellular apparatus that aids the transport of secreted proteins across the endoplasmic reticulum. Subsequently nucleotide sequence analysis revealed that parts of the 7SL RNA sequence seem to derive from the *Alu* element², which is repeated about 300,000 times in the human genome³. While *Alu* is usually found as a head-to-tail dimer of a sequence about 150 base pairs long, in the 7SL sequence a single *Alu* monomer seems to have suffered an insertion of 155 base pairs. This was not in itself a dramatic discovery because *Alu* elements are dispersed so widely throughout the human genome that they could easily be a target for random DNA insertion. However, the latest developments concerning *Alu* and 7SL RNA^{4,5}, some of which are published on page 171 of this issue, have taken a quite unexpected turn.

Ullu and Tschudi⁴ have sequenced 7SL RNA (as a DNA clone) from *Xenopus* and *Drosophila*. Both are clearly related to the human counterpart throughout their length — that is the sequence homology extends to the *Alu*-like part of the human molecule. The presence of an *Alu*-like sequence in *Drosophila*, also found by Gundelfinger *et al.*⁵, means that *Alu* has had a much longer evolutionary history than was previously thought. More interesting yet, in *Drosophila* it seems only to exist as part of the 7SL DNA, of which there are two copies. On this basis, Ullu and Tschudi suggest that *Alu* sequences represent defective 7SL RNA molecules that have been reverse-transcribed into DNA and inserted into the genome. An analogous origin has been suggested for alpha-globin pseudogenes in the mouse⁶, and the multiple pseudogenes for small nuclear RNAs in man⁷. Pseudogenes are generally thought not to play an important role in the cell. Perhaps those who have argued that *Alu*, by its very abundance, must have an important function will recognize that this argument has now lost some of its weight.

Although it seems likely that the 7SL sequence with its single *Alu* evolved in the absence of repeated *Alu* elements, an alternative interpretation of Ullu and Tschudi's data presents itself, at first sight. In the 7SL-specific region of the sequences the match between the human and *Drosophila* sequences is 67 per cent, and the correct alignment is obvious. In the *Alu*-related re-

gions the degree of match is less and the two groups opt for rather different alignments, especially at the 3' end. If, in fact, these regions of the sequence are completely unrelated, then the earlier hypotheses could still be tenable. However, using the method of Fitch and Smith⁸, I find that the alignment of the *Drosophila* sequence with the 3' *Alu*-related part of the human 7SL sequence suggested by Ullu and Tschudi has a probability of less than 0.01 of occurring by chance. Thus the flanking regions of the *Drosophila* 7SL RNA are homologous to *Alu* in man and the *Alu* sequence first existed as a part of this molecule.

As expected, for *Xenopus laevis* the overall match with the human sequence is much higher⁵ than either is with *Drosophila*, although it drops off in 3' *Alu*-related region. Although their previous results indicate only weak homology to *Alu* in *Xenopus* DNA⁹, Ullu and Tschudi describe the *Xenopus* genome as being 'rich' in sequences related to the *Alu*-like parts of the *Xenopus* 7SL molecule. So, in *Xenopus* as well as man, there is a close relationship between the 7SL RNA and highly repetitive elements, although the *Xenopus* and human sequences have diverged during evolution. How did this relationship arise? The fact that 7SL has a longer evolutionary history, being found in the absence of any *Alu*-related repeats in *Drosophila*, strongly suggests it was the antecedent. Moreover, the 7SL RNA is arranged in the signal recognition particle in such a way that three RNA fragments similar to the 5' *Alu*-related, 7SL-specific and 3' *Alu*-related sequence domains are generated by limited enzymatic digestion of the intact particle¹⁰. Put that together with the circumstance in which the 7SL RNA was first discovered — in a retroviral particle¹¹ and therefore close to a source of reverse transcription activity — and the generation of DNA copies of *Alu* is easy to imagine.

Amplification

Once *Alu* had appeared, what happened next? It has been known for some time that *Alu* is a remarkably stable component of the genome. Having arisen at a specific location, it does not seem to disappear quickly. For example, in the gamma-globin region, two *Alu* elements are present in exactly the same place in both man and chimpanzee¹². This is in striking contrast to the vagility shown by the middle repetitive DNA elements in *Drosophila*, and until now there has been no real explanation for the difference. However, if *Alu* originated

as a 7SL pseudogene it may not possess or respond to any mechanism for excision or transposition. Thus, unless it kills the chromosome in which it inserts, it might just have to stay there. If it retains polymerase III promoter activity (not all copies do retain it), it could even generate more transcripts, each of which might be another possible template for reverse transcription and reinsertion. One would therefore expect copies to accumulate in the genome.

Two questions are left. First, did the events which gave rise to the *Alu*-related repetitive elements occur once in each of the *Xenopus* and human lineages independently? If so, it might explain the sequence divergence between repeats of the two species; within the species the repeat sequence very closely resembles the 7SL sequence. However, we should remember that some concerted evolution has probably taken place. It is possible to envisage repeats already existing in the primitive amphibian DNA and gradually, after the two lineages separated, changing *en bloc*. Any subsequent generation of pseudogenes would be of the species-specific 7SL sequence; a process of concerted evolution which kept the 7SL and *Alu*-related repeats reasonably similar within each species is not unlikely.

The second question is, why has none of this occurred in *Drosophila*? Here there are no easy answers. The situation is similar to the case of the small nuclear RNAs, where many pseudogenes are found in man⁷, but not in *Drosophila*¹³. Processed pseudogenes of protein coding regions also seem to be absent in the fly. There is certainly no absence of reverse transcriptase activity which might explain this — generation of reverse transcripts may be a major mechanism for replication of *copia*¹⁴. Nevertheless, reverse transcripts do not accumulate in the genome of *Drosophila* in the way they have in vertebrates. When we know why this is so, we shall be well on the way to understanding why the genomes of insects are so very much smaller than those of vertebrates despite containing much the same amount of information. □

Towards a model for the arms race

SIR — Saperstein's use of a discrete recursion model to describe the arms race¹ is intriguing. He uses equations derived from the study of chaotic behaviour, as manifested in fluid dynamics. We have two theoretical objections, but in addition, his model's predictions do not agree well with the available data.

The model states:

$$x_{n+1} = 4ay_n(1 - y_n) \quad (1)$$

and

$$y_{n+1} = 4bx_n(1 - x_n) \quad (2)$$

where y_n represents the ratio of arms expenditure to Gross National Product (GNP) in country A (say the Soviet Union) in the year n , and x_{n+1} represents the same ratio for country B (say the United States) in the following year. The stability of the arms race is predicted from the disposable parameters a and b .

According to these equations, as the expenditures of nation A approach its GNP, those of nation B approach zero. This does not seem reasonable. A kind of saturation term might be preferable, but would probably not produce the "chaotic" behaviour desired.

Although the ideas are linked semantically, the chaos of warfare and of fluid dynamics are otherwise dissimilar. In warfare, the variables representing arms expenditures do not undergo a transition to a wandering unpredictable distribution, as the equations imply. Predictably, they will show a dramatic increase.

In his examples of various arms races, Saperstein gives data for only two years. For the Soviet Union and the United States, data are available² for the 10-year span 1971 to 1980 (see table below). To compute a least squares estimate for the parameter b requires minimizing the function

$$f(4b) = \sum_{i=1}^{n-1} [4bx_i(1 - x_i) - y_{i+1}] \quad (3)$$

Setting $f'(4b) = 0$, the function has a minimum at

$$4b = \frac{\sum_{i=1}^{n-1} [x_i(1 - x_i)(y_{i+1})]}{\sum_{i=1}^{n-1} [x_i(1 - x_i)]^2} \quad (4)$$

This gives $4b = 2.55$, or $b = 0.64$ (compared with 0.54 as estimated by Saperstein.) Similarly, $4a = 0.467$, or $a = 0.12$ (compared with 0.15). After transforming

the variables in the nonlinear equations, linear regression can be performed:

$$y_{i+1} = 4bX_i, \text{ where } X_i = x_i(1 - x_i) \quad (5)$$

and

$$x_{i+1} = 4aY_i, \text{ where } Y_i = y_i(1 - y_i) \quad (6)$$

Equation (5) represents the prediction of Soviet expenditures based on previous US expenditures, and equation (6) the reverse.

The correlation coefficient measuring agreement between the model and the actual data is given by

$$r^2 = SS_{\text{regression}} / (SS_{\text{regression}} + SS_{\text{residuals}}) \quad (7)$$

where

$$SS_{\text{regression}} = \sum_{i=1}^{n-1} (4bX_i - \bar{y})^2, \quad (8)$$

$$\bar{y} = 1/(n-1) \sum_{i=2}^n (y_i) \quad (9)$$

and

$$SS_{\text{residuals}} = \sum_{i=1}^{n-1} (y_{i+1} - 4bX_i)^2 \quad (10)$$

For the prediction of Soviet expenditures from those of the United States, $r^2 = 0.518$. Analogously, the prediction of US expenditures from those of the Soviet Union gives $r^2 = 0.130$. A plot of the residuals demonstrates a clear trend, indicating a systematic error in the model.

For comparison, Hamblin³ obtains correlation coefficients better than 0.9 in applying his curvilinear model to arms expenditures before the First World War, to "warlike worktime" before the Second World War and to satellite launchings, ballistic missile production and nuclear explosions in more recent times. These data sets are more accurate than the proportion of GNP devoted to arms, which rests on many assumptions. The asymmetry of Hamblin's model (in contrast to Saperstein's) has serious policy implications: he assumes one party to the arms race to be the leader.

While Hamblin³ and Richardson⁴ discuss the possible meaning of their parameters, Saperstein unfortunately does not speculate on what might influence the values of a and b , and hence the stability of the arms race. We share his concern that we may be closer to the threshold of war than the model suggests, especially considering the magnitude of actual expenditures rather than the theoretical parameters. The proportion of resources devoted by the

Soviet Union to arms has been matched in peacetime only by that of Nazi Germany just before the Second World War.

Basement membranes and epithelia

SIR — There is considerable confusion over the nomenclature of "basement membranes" of epithelia. We propose, in accordance with usage in a number of leading laboratories, to restrict the term *basement membrane* to the (usually) fibrillar layer produced by the connective tissue fibroblasts, and to use the term *basal lamina* only for the acellular glycocalyx immediately underlying the epithelial cells. The basement membrane can always be resolved by light microscopy, the basal lamina as a rule only by electron microscopy. The distinction is a morphological and operational one and as such is perfectly unambiguous. (We leave aside the question whether the basal lamina may be regarded as part of the basement membrane.)

Gene conversions and crossing-over

SIR — Fink and Petes¹, in their News and Views commentary on the interesting papers by Klein² and by Klar and Strathern³, refer repeatedly to the "50 per cent rule" relating gene conversion to crossing over and state that this rule has been so compelling as to have been "incorporated into virtually every current model of recombination". This may give a wrong impression. As Klein points out, it has long been known that intragenic recombination at meiosis within certain genes in various eukaryotes may involve crossing over far less than 50 per cent of the time. An association of as low as 10 to 30 per cent is not at all unusual in *Sordaria*⁴, *Neurospora*⁵ and *Drosophila*⁶. Even in *Saccharomyces*, as Stadler pointed out in his 1973 review⁷, the figure comes down to 35 to 40 per cent when proper allowance is made for coincidental crossovers.

It would be remarkable if virtually every current model really were committed to a 50 per cent rule, and in fact this is not so.

Proportion of GNP devoted to arms expenditure

Year	United States	Soviet Union	Year	United States	Soviet Union
	x_i	y_i		x_i	y_i
1971	0.070	0.144	1976	0.053	0.134
1972	0.066	0.147	1977	0.053	0.131
1973	0.060	0.142	1978	0.051	0.142
1974	0.061	0.142	1979	0.051	0.143
1975	0.059	0.144	1980	0.055	0.146

The model proposed in 1975 by Meselson and Radding⁸, which was put forward for quite another good reason (the need to reconcile the Holliday model with the increasingly strong evidence for hybrid DNA on one participating chromatid only), provides a very plausible way of uncoupling conversion from crossing-over to any desired extent. According to this model, the first step leading to gene conversion is the unilateral invasion of one participating chromatid (DNA duplex) by a single DNA strand unwound from the other. The reciprocal strand-crossing and the formation of the symmetrical cross-strand structure (Holliday junction), which hypothetically sets up the possibility of crossing over, follows later after a series of manoeuvres that could easily require special conditions (such as may prevail more or less during meiosis) for their efficient performance. An apparently easy alternative is for the initial single bridge to be cut by an endonuclease, the invading single-strand fragment ligated into the recipient chromatid and the gap in the donor chromatid filled by repair synthesis. This could lead to conversion without any possibility of crossing over.

Since crossing over (both in fact and in theory) can be so easily uncoupled from conversion even in regular meiosis, it is no surprise to find it largely avoided during genetic exchange between repetitive sequences at non-homologous loci, when its occurrence would lead to highly deleterious chromosome rearrangements. But perhaps it is not avoided completely. Spontaneous chromosome aberrations do occur at a low frequency, and something like a "0.1 per cent rule" governing interactions between dispersed repeats could account for many of these.

SIR — Fink and Petes¹ in writing on gene conversion make repeated reference to a so-called 50 per cent rule. According to this, half the intragenic conversion events in fungi are associated with reciprocal recombination. These authors imply that there is compelling evidence for this conclusion. In reality there is much variation in the frequency with which aberrant segregation is associated with reciprocal exchange, with values ranging from 15 per cent to 75 per cent (see ref. 2, p. 321). Only one example seems to be known of a satisfactory fit with 50 per cent, namely, aberrant 4:4 segregation at the *g* spore

colour locus in *Sordaria fimicola*^{3,4} (and see ref. 2, p. 240).

Klar and Strathern⁵ have discovered that conversion involved in yeast mating type switching during the mitotic cycle is not associated with reciprocal exchange and Klein⁶ has made the same discovery for meiotic intrachromosomal conversion between duplicated inverted sequences at the *HIS3* locus, also in *Saccharomyces cerevisiae*. Fink and Petes¹, in commenting on these results, overlook the evidence of various kinds from organisms as diverse as *Drosophila melanogaster*^{7,8}, *Secale cereale* (rye)⁹ and several fungi¹⁰⁻¹³, that eukaryote recombination may be a two-step process, with gene conversion events in the first step and reciprocal exchange in the second (see ref. 2, pp. 324, 336, 343). The results obtained by Klar and Strathern⁵ and Klein⁶ could then be accounted for if intergenic recombination differs from the normal process in lacking the second step.

Snookered by colour differences

SIR — Your correspondent William Hickmott (*Nature* **310** 731-732 1984) reported a hitherto unrecognized property of colour. My own part-time socio-physiologico-behavioural research, carried out over many years, lends further weight (*sic*) to the hypothesis proposed, although my extensive data, collected for a different purpose, reveal a different ordering. My research has been on the influence of the recreational context on the liquid consumption of the adult human male.

From the mass (*sic*) of data which I have accumulated I extracted the small subset relating to a particular recreational activity in which pairs of males use sticks to strike small spheres of identical size on a large green rectangular surface. Naturally, in order to minimize the "Hawthorne" effect I have always observed from a great distance (~10³ cm) and have never enquired as to their purpose. (I opine that they are amateur physicists constantly testing and retesting Newton's laws of motion. Their efforts are, however, constantly frustrated since the experimental surface has a number of

roughly circular defects into which spheres frequently disappear.)

All this brings me to the point of my observations. The spheres are of different colours, presumably to facilitate their differentiation in the heavily polluted atmosphere in which these experiments usually take place. The behaviour of these spheres is most curious and for a long time the reason eluded me, but it can be explained now by your correspondent's hypothesis.

The red spheres behave most oddly of all — when they disappear down a defect in the experimental artefact they are not reused, unlike the other coloured spheres. (This correlates well with your correspondent's observations of the red tomato, and suggests that the effect of this colour is so great that the objects are more easily damaged.) As the red spheres disappear the effect of the other coloured spheres is more easily discernible, although the effects are exceedingly complex.

My computer analysis of the results has led me to the inescapable conclusion that the colours do indeed display action at a distance. The disappearance of the colours, usually temporary, triggers a behavioural response in the males which manifests itself in the physical moving of pointers on a scale displayed on the wall near the experiment. I have no idea of the function of these scales, but they may be of symbolic or ritualistic significance.

From my analysis (Imperial undimensional scaling), I conclude that the order of the colours is: red, yellow, green, brown, blue, pink and black, with white occupying an anomalous position on a dimension normal to this. This seems to be almost completely the opposite of the ordering which your correspondent reported, but this need not cause us to reject his basic hypothesis.

The answer clearly lies in the observations discussed by John Maddox (*Nature* **310**, 723; 1984) — the inverse square law needs to be generalized to an inverse sphere law in the complex situation where more than two bodies are involved. As a corollary, the colour of the spheres in the experiments to measure *G* is probably the reason for the variations observed.

Scientific Correspondence is intended to provide a forum in which readers may raise points of a rather technical character which are not provoked by articles or letters previously published (where Matters Arising remains appropriate).

Forest succession

The once-standard holistic theory of forest succession has more recently been overtaken by a Neodarwinian reductionist theory with defects of its own. A less inflexible theory is much needed.

THE term succession is used to describe many types of vegetation change on widely different scales in both space and time. In discussing forested or potentially forested zones, succession is formally defined here as the directional change with time of the species composition and vegetation physiognomy of a single site where climate remains effectively constant. Understanding succession is important for two reasons—the value of the concept in the development of ecology as a science and its enormous potential in the development of programmes for the conservation and exploitation of biological resources^{1,2}. Succession is nevertheless a most controversial issue, involving confrontation between holism (the view emphasizing unity and integration in nature), and reductionism (in which chance and darwinian interpretations dominate).

Primary successions occur on previously unvegetated terrain. Glacial moraines in Alaska, for example, eventually support spruce forest after first being colonized by herbaceous plants, which are succeeded by thickets of willow and alder. Secondary successions occur on disturbed areas, including those converted to agriculture and subsequently abandoned. In parts of the east coast of the United States, the herbaceous communities of such 'old fields' are quickly invaded by pines and then by oak, hickory and other species characteristic of the original forests of the region. Environmental changes occurring during succession are classed as autogenic when they are a consequence of the presence of plants. Examples are the accumulation of organic matter in soil and the modification of light levels within vegetation. Allogenic changes, on the other hand, are those caused by factors external to the vegetation. Examples include the deposition of silt by rivers and local temperature changes as glaciers retreat.

No direct study of forest succession has so far been possible because of the longevity of the organisms involved. Descriptions of succession are usually inferred from studies of the vegetation of adjacent sites of different known ages, in which case it is necessary to assume that sites differ only in age and not in substrate material, climatic history, past disturbance or the input of propagules. Although often reasonable, the validity of this assumption is not always carefully assessed³; descriptive field studies rarely provide much insight into the mechanisms of successional change, which remain hypothetical and are a major concern of the long-standing theoretical controversy over succession.

Theories of succession

The development and interrelationships of holistic and reductionist theories have been reviewed by McIntosh^{4,5} and these are briefly summarized and contrasted here. Common to both theories, however, is the natural history of trees. The broadest distinction that can be made between tree species participating in successions is between 'pioneer' trees, those species usually most prominent on open sites and absent from forest, and 'forest' trees, individuals of which contribute to the canopy of mature

forest. The classification^{6,7}, summarized in Table 1, may be a 'crude oversimplification' (see ref. 8), but it is necessary for presentation of the general arguments on succession⁹.

Holistic ecology takes the ecosystem, a unit of environment and biota in reciprocal interaction¹⁰, as its object of study. Ecosystems are held to possess 'emergent' properties—properties which cannot be inferred from those of the parts of the system. Successional change is often considered to occur in stages through wave-like invasions by groups of species, and is thought to be controlled by the vegetation itself. Thus autogenic change, caused by the presence of a particular species or group of species, makes the environment suitable for the next group of species and so facilitates successional change. This is the 'facilitation' hypothesis. In holistic theory, the development during succession of 'biological control' of nutrient cycling is also emphasized. Succession is interpreted teleologically as the process of development of an ecosystem of maximum stability (by the yardstick of resistance to disturbance) and of maximum efficiency in the utilization of resources¹⁰. Successional change is usually held to be orderly, predictable and therefore deterministic, converging to forest from various different starting points.

Table 1 Empirically determined attributes of pioneer and mature forest tree species

Characteristic	Pioneer tree	Forest tree
Dispersibility of seed	To long distances wind/bird/bat	Short distance rodent/bird/none
Seed weight	Light to heavy	Relatively heavy
Seed germination: light-stimulated	Yes	No
inhibited by far red light	Yes	No
Longevity of individual	Shorter	Longer
Time to repro- ductive maturity	Shorter	Longer
Height growth	Fast	Slow
Height at maturity	Shorter	Taller
Resource acqui- sition rates	Fast	Slow
Photosynthesis light-saturated at	High light intensities	Low light intensities
Recovery from resource limitation	Fast	Slow

These categories represent the extremes of a spectrum of ecologies; pioneer is analogous to 'r-selected', forest to 'k-selected'. Reductionist authors assert that these differences between pioneer and mature forest species explain all the phenomena of succession (see also Fig. 1) (from refs 7 and 8).

In the past decade, the defects and lack of applicability of holistic theory have been convincingly exposed and a new body of reductionist theory has developed¹¹⁻¹⁶ based on Gleason's interpretation of the plant community as a fortuitous assemblage of species populations, each with a unique behaviour¹⁷. The fundamental stochasticism of this view is supported by evidence of several alternative successional pathways within a given vegetation type¹⁸. The cornerstone of the new successional theory is the modern interpretation of Egler's¹⁹ initial floristic composition (IFC) model (Fig. 1). In this model all the species participating in a succession become established at or very shortly after initiation. Succession is merely the sequential physiognomic dominance of the site by species with different life histories, growth rates and sizes at maturity. The facilitation hypothesis is rejected, and autogenic changes are seen as neutral or inhibitory factors rather than the driving force of succession. The theory emphasizes that the availability of resources may decrease with succession as the density of individuals increases. Pioneers are seen as opportunists exploiting environments free from 'competition', while forest trees are efficient and conservative in their use of resources. This interpretation of autogenesis has resolved into two subsidiary models, 'tolerance' and 'inhibition', considered more fully below. Although a reductionist, darwinian approach^{20,21} has given great impetus to contemporary plant ecology, enjoying the heuristic advantages inherent to reductionism, the new successional theory has developed independently of this mainstream and rests not on new empirical findings, but on reinterpretations of existing data. Unease has already been expressed at this development^{4,5,22}; is there progress if models such as IFC, tolerance and inhibition simply replace the holistic framework as the dogma by which inadequate field data are interpreted?

This review is a critical appraisal of the theory as it now stands, and suggests a better approach in considering succession. The ideas developed in references 11-18 will be referred to as the 'reductionistic approach' and their authors as 'the reductionists'.

Reductionist succession

Tolerance is the ability of individuals (particularly of juveniles) to survive in the poor environmental conditions resulting from the high density of other individuals. Foresters have long been aware that tree species differ in their ability to become established and grow within a forest^{23,24}. Although this may be due in part to factors affecting the availability of soil moisture and mineral nutrients, tolerance has come to be synonymous, in successional theory, with the ability to persist or grow in shade. By this definition, pioneer species are intolerant and forest species tolerant, because pioneer trees cast shade, thereby preventing their own regeneration and are replaced by forest trees, which can become established in the shade. It is well known that felling stands of intolerant pines on old fields increases the growth of the tolerant juvenile forest trees in the understorey, raising the suggestion that autogenic change (shading) delays rather than facilitates succession¹¹. Unfortunately, however, removing the understorey also increases the growth of pines²⁵, introducing the first constraint on this simple model.

Some have nevertheless unacceptably adopted tolerance as the sole mechanism of forest succession^{26,27}. Tolerance is clearly an essential component of the biology of forest trees. However, it being the only mechanism of succession depends on whether environmental factors other than quantum flux are limiting to establishment and growth, whether the states of these factors change as succession proceeds and whether pioneer and forest species differ in their responses to these environmental changes. At the outset, the possibility must at least be considered that juveniles of some forest trees not only tolerate the environment of a pioneer forest canopy, but require it. Silvicultural experiments in the rain forests of Malaysia, for example, have shown a wide variation between species in the responses of apparently suppressed saplings to the clearance of canopy trees⁸. The growth of some species accelerates, as the tolerance model

Fig. 1 Schematic representation of the initial floristic composition model of succession. Species 1-5 become established at the initiation of the succession, and successively dominate the site due to the different lengths of time they take to reach maturity. Species 1 may represent an annual herb, species 4 a short-lived shrub, and species 5 a slow-growing, shade-tolerant forest tree. Species 1-4 fail to regenerate as they are light-demanding. Late colonization by species 6 occurs as a consequence of the release of the inhibitory effects upon it of species 3 (modified from Gómez-Pompa and Vásquez-Yanes³⁹).

predicts, but individuals of other species become stunted, susceptible to disease or predation, or are killed.

The inhibition model proposes that the vegetation occupying a site prevents the invasion of other species. The best evidence for this model is the demonstration of apparent long-term stability in certain vegetation types, mainly monospecific stands of clonally spreading shrubs¹³. These areas may not be typical; they are usually small or extremely small, and sometimes have an unusual management history. Thus inhibition may not be a general phenomenon in forest succession; more work is required to establish the frequency with which it occurs.

Initial floristic composition

Initial floristic composition (IFC) has become accepted as a descriptive model for both primary^{4,16} and secondary successions¹¹. Although this model fits field observations more closely than did holistic ideas, it is certainly not an explanation, nor even a general description, of succession. Niering and Goodwin suggest¹³ that, with respect to North American old field successions, IFC requires 'conceptual elaboration' and go on to include the supposedly more general cases in which woody species are not present at the initiation of successions, but appear within a few years. This elaboration neither describes nor explains the behaviour of many forest tree species.

There is a substantial body of information about old field successions in several forest regions of the United States. Two groups of woody species consistently appear within 10 years of the abandonment of a field. The first comprises short-lived shrubs and small trees, and is exemplified by the species of *Prunus* and *Juniperus* recorded on recently abandoned fields in New Jersey²⁸⁻³⁰. The second group consists of larger and longer-lived trees which may also occur as components of mature forest. In the Carolinas and southern Virginia, this group includes loblolly pine (*Pinus taeda*) and shortleaf pine (*Pinus echinata*), which may appear in large numbers after one year, the density of seedlings depending on the proximity of parent trees^{31,32}. Red maple (*Acer rubrum*) behaves similarly²⁹. Despite the claims of Niering and Goodwin¹³ and others, it is clear that almost all the oaks (*Quercus* spp.) and hickories (*Carya* spp.) characteristic of the mature forests of many of the central and eastern states of the United States are significantly later colonizers of old fields. Colonization by oaks has been recorded between 11 and 20 years after the abandonment of fields²⁸⁻³⁶, except in two cases in which very early colonization was induced by the presence of overhanging parent trees^{37,38}. Longer periods of time elapse before the appearance of hickories; sites abandoned for 40 and 60 years are amongst the most recent from which new individuals have been reported^{33,34}. (The one exception is a record of hickory

seedlings after three years on one of the 10 sites monitored over 11 years by Buell *et al.*²⁸, but further colonization has not been reported during this continuing study³⁰.) In all the cases cited, colonization by oaks and hickories occurred on sites already supporting established pioneer vegetation.

Studies of secondary forest succession in the humid tropics have been ignored by the reductionists. The 'old fields' of the tropics are forest clearings abandoned by farmers practising shifting cultivation. It is generally accepted that species of late successional and mature forests do not colonize such clearings until there is already a well established pioneer vegetation, dominated by fast growing pioneer trees^{2,8,9,39-41}.

In England, primary successions in abandoned quarries recently received some attention in a study of the vegetation of three chalk quarries⁴². Birch (*Betula pendula*) and willows (*Salix* spp.) are able to behave as pioneers on bare chalk, while hawthorn (*Crataegus monogyna*) and English oak (*Quercus robur*) are clearly later colonizers, appearing once the sites already support pioneer scrub (Fig. 2). A survey of 48 chalk and limestone quarries throughout the country suggests that this pattern of colonization has been repeated several times⁴³.

On many sites undergoing succession, the seedlings of shrub and tree species such as *Crataegus* and *Prunus* spp., and the tropical genus *Cecropia*, exhibit markedly clumped distributions, occurring mostly under the canopies of established trees^{42,44-49} (see Fig. 3). These species may be very early colonizers of abandoned sites, such as orchards which already support trees^{44,45}, or later colonizers in primary successions, such as those occurring in abandoned chalk quarries⁴².

Different tree species seem not to have become established simultaneously at the initiation of any of the successions described here, so that the simulational and predictive power of IFC would appear to be limited. Differential seed dispersal is probably chiefly responsible for the failure of this model, but this does not imply that it is sufficient to regard dispersal simply as a stochastic process in which light wind-dispersed seeds will usually go further in a shorter time. The role of animal dispersal vectors will be crucial to the colonization of successional sites by many woody species. Of the pioneer trees mentioned, the pines, maple, birch and willow all have wind-dispersed seeds⁵⁰, while those of tropical forest pioneer trees are widely dispersed by birds and bats^{51,52}. Oaks, hickories, other temperate forest species such as beeches, and many of the trees of undisturbed humid tropical forests have large short-lived seeds^{50,53,54} which lack the fleshy pulp and other characteristics of seeds specifically attractive to dispersal vectors, but which are nevertheless dispersed by the hoarding behaviour of forest rodents and birds⁵⁵. It is probable that many such forest vertebrates do not enter open fields or clearings except on brief forays from surrounding hedgerows or forest, as in the case of the red squirrel (*Tamiasciurus hudsonicus loquax*)⁵⁶. Acorns are a major component of the diet of the jay (*Garrulus glandarius*), which buries them in forest, open woodland or around isolated trees, but avoids open fields^{57,58}. The genera *Crataegus*, *Prunus* and *Cecropia* all bear fleshy fruits, dispersed by frugivorous birds (and bats, in the case of the tropical taxon). It is likely that in all these cases, colonization of a site requires the presence of trees in which the dispersal vectors may roost^{42,44-49}; similar considerations may apply for the dispersal of the many species of canopy trees in humid tropical forest.

These observations are consistent with the hypothesis that the presence of pioneer woody species often increases the rate of colonization of a site by other woody species whose seeds are dispersed by animals and birds since the pioneers render the site more attractive to dispersal vectors (see also ref. 59). The behaviour of the vectors is probably decisive; bird-dispersed shrubs do themselves behave as pioneers on old fields in the United States^{28-30,60} and in England⁶¹. The testing of this hypothesis would be welcome.

The few known successions which actually resemble IFC are of two types. The first is where forest species with wind- or ballistically-dispersed seeds dominate the local flora, as in the

Fig. 2 Succession in abandoned chalk quarries in southeastern England. Histograms represent the age structures (excluding first year seedlings) of populations of birch (*Betula pendula*, open bars), oak (*Quercus robur*, vertical lines) and hawthorn (*Crataegus monogyna*, stippled) in representative stands on the three adjacent quarries, in August 1982. Vegetation was homogenous at the scale sampled, removing species/area effects. a, Site abandoned for approximately 7 years; b, site abandoned for ~35 years; c, site abandoned for ~60 years. Birch is a primary colonizer, appearing before abandonment of the sites. Oak and hawthorn are much later colonizers; oaks in c were well formed, some attaining the height of the oldest birches. Seedlings of hawthorn were recorded in a in 1982 (Fig. 3). The inset in b records another part of this site and illustrates spatial variation in colonization. Although these data show populations each with an individualistic behaviour, they do not conform to the IFC model.

upland evergreen forests of Ghana⁶², on mudflows in Californian river valleys⁶³, and on Alaskan glacial moraines. (Other factors affecting moraine successions, however, would seem to limit the value of IFC in even this case, as will be shown below.) The second is the regrowth of forest after clear-cutting, when the succession is dominated by pioneer trees from viable seeds already present in the soil and the regrowth of forest species from stumps⁶.

The role of autogenic change

Implicit in the reductionistic approach is the assumption that different tree species are equally able to become established and develop normally in the environment of a newly available site. The reductionists, however, carefully do not analyse contradictory evidence, probably because it leads towards the facilitation model. Drury and Nisbet cite undeniable evidence for the role of allogenic change¹¹, but their attempt to refute the hypothesis that autogenic soil development plays a role in primary succession does not succeed. Botkin emphatically concludes that the elements of the reductionistic framework (as defined here) are sufficient to account for all the phenomena of succession⁶⁴. His computer simulations reproduce the growth of established individuals of different tree species on mature soils, so that it

is scarcely surprising that environmental changes other than shading were found to be unimportant. A large body of observations made in other circumstances remains to be incorporated into the reductionistic framework. Part of the difficulty is that the evidence is scattered in a wide range of sources, and is not always directly related to succession. This is unavoidable in a field where progress towards understanding the mechanisms at work has only just begun⁶⁵.

Harper provides a basis for understanding the recruitment of seedlings²¹. A germinating seed occupies a 'safe site', a microenvironment which provides, for example, dormancy-breaking stimuli, the resources necessary for germination (particularly water and oxygen) and freedom from predators and pathogens. Microenvironmental heterogeneity can have dramatic effects on seed germinations which varies between species in a manner related to the different sizes and shapes of the seeds. Environmental factors affecting the survival of seedlings include the availability of moisture, temperature variations and predators. All of these factors may be modified by the presence of neighbouring plants, and each is subject to autogenic change during succession. The accumulation of organic matter in the surface layers of the soil during forest succession on old fields and the floors of abandoned chalk quarries increases the retention of moisture in the zones most affecting seeds and seedlings^{32,42,66}; this is probably a feature of all successions in which organic soil horizons develop. In the humid tropics, diurnal soil and air temperatures and saturation deficits of the air, are all lower in forests than in open clearings, largely because of shading⁶⁷⁻⁶⁹. Indeed, such spatial environmental heterogeneity is a general feature of forest microclimates⁷⁰, and the kind of environmental changes to be expected during succession can be extrapolated from these findings. Pioneer and forest species may, however, differ in their responses to these autogenic changes, as will now be examined.

Generalizations are not possible from studies of the environmental requirements and tolerances of pioneer trees colonizing clear-felled forest sites where removal of forest trees is assumed to increase the availability of water and mineral nutrients. The pioneer trees of primary successions do not enter an environment with the freely available resources of clear-felled forests; neither, it would seem in some cases, do those colonizing old fields.

Within young, primary successional birch woodland (Fig. 2, site b), the mortality of seedlings of birch and willow is higher on bare chalk than in gaps in a turf of mosses and herbaceous plants⁴². In a neotropical secondary succession, the recruitment on bare soil of seedlings of the pioneer tree *Cecropia filicifolia* was markedly increased by treatments which reduced surface temperatures and evaporation⁷¹. It seems certain that tolerance of periodic drought and other environmental extremes is a critical factor in the survival on old fields of pioneer loblolly pine, red cedar (*Juniperus virginiana*) and elm (*Ulmus alata*)^{72,73}. (An important component of the biology of seedlings of pioneer species is that they should be tolerant of, or have a mechanism to avoid, high leaf temperatures induced by short-wave solar radiation at exposed sites⁷⁴.) Examples of sites which become dominated by pioneer species suggest that this occurs by toleration, not by exploitation of the environment.

There are very few critical studies on the establishment of forest trees in pioneer environments but there is much evidence to suggest that forest species do not have the ability of pioneers to become established there. Acorns are readily killed by heat, desiccation or winter frost when surface-sown on open sites⁷⁵⁻⁷⁷. Germination requires burial, to protect acorns against environmental extremes, to facilitate uptake of water and to protect them from seed predators, a major cause of mortality⁷⁶. These characteristics are probably shared by all large tree seeds, providing the first potential barrier to establishment on open fields and clearings in temperate and tropical zones.

The next potential barrier may occur at the seedling stage since seedlings of red and white oaks (*Quercus rubra* and *Q. alba*) are intolerant of drought and do not survive on drier forest sites⁷⁸; survival of red oak seedlings planted on coal spoil

Fig. 3 Separation of seedlings of three tree species along a spatial gradient in ground cover of leaf litter in site a of Fig. 2, September 1982. Data are summarized from 60 quadrats of 0.25 m², 10 randomly positioned in each of six 25-m² stands of birth/willow scrub. All quadrats in the 81-100% litter cover class were directly under the canopies of willow bushes. The seeds of birch (vertical lines) and willow (open bars) are widely dispersed by wind, but bare ground is required for the establishment of seedlings of these species. The distribution of hawthorn seedlings (stippled bars) is probably a consequence of patterns of seed deposition by frugivorous birds perching in established bushes.

is greatly improved by treatments reducing the high surface temperatures and the incidence of moisture deficits⁷⁴. On a Michigan old field, seedlings of *Quercus velutina* and *Q. alba* survived when established among herbaceous vegetation, but not on bare ground⁷⁹. Even within forest, seedlings of beech (*Fagus grandifolia*) occur much less frequently on dry south- and west-facing slopes than on those facing north and east⁸⁰. European beech (*F. sylvatica*) does not establish from seed on open ground⁸¹; *Agathis australis* in New Zealand requires the presence of associated shrubs⁸². Shade may be required for the successful establishment of seedlings of tropical forest trees of the family Dipterocarpaceae⁸, possibly as a consequence of intolerance of drought and high saturation deficits, and of the high leaf temperatures likely to be experienced in full sunlight.

Traditional theories assign autogenic development of soil and mineral nutrient cycling a functional role in two types of forest succession—secondary successions on abandoned shifting cultivation clearings in humid tropical forests, and primary successions on substrates such as glacial moraine. In the former type, forest clearings are abandoned when they will no longer produce a useful crop, partly because of loss of soil fertility. The ecological implications of this have been discussed². After abandonment, the site is often invaded by pioneer trees and improvements in soil fertility take place, which has been demonstrated on sites in Nigeria and Ghana^{83,84}. Sites where such an increase in soil fertility does not occur, such as are found in Costa Rica⁸⁵ where the soils are unusually fertile⁸⁶, may well be atypical. Extrapolating from Jordan and Herrera's⁸⁶ conclusions, it is possible that in the humid tropics facilitation may operate in successions on less fertile soils such as those of the Amazon basin, which are intensely leached. Much work remains to be done to resolve this issue.

The major early constraints on plant growth during primary succession are common to all environments; a lack of available macronutrients such as nitrogen and phosphorus and a lack of soil organic matter^{42,59,87-98}. In physically extreme environ-

Fig. 4 Composite mechanisms of succession. The tolerance model operates in all examples, as light-demanding pioneer trees fail to regenerate. Inhibition, tolerance and facilitation affect the colonization and development of forest trees. *a*, Seed dispersal vectors of a large seeded forest tree do not enter a site until pioneer vegetation has developed sufficiently to provide a habitat attractive to them. The seeds germinate but the seedlings do not develop in the environment of the pioneer vegetation; the seedlings are, however, protected from the potentially deleterious effects of direct sunlight. The seedlings develop to maturity on the deaths of individual pioneers. Facilitation operates at the seed dispersal stage, tolerance and facilitation simultaneously at the seedling stage. *b*, A nitrogen-fixing pioneer and a forest species become established simultaneously on an extremely infertile mineral substrate. Shade-tolerant juvenile forest trees in the pioneer thicket benefit from the nitrogen fixation and other environmental changes consequent on the presence of the pioneer. Open growth forest trees develop more slowly, and are overtopped both by 'nursed' individuals and by later colonizers. Facilitation and tolerance operate at the juvenile stage, although open grown forest trees may also develop to maturity. *c*, A similar situation to *b*, but forest trees are unable to become established in the pioneer thicket, colonizing the nitrogen-rich environment left after the deaths of the pioneers. Inhibition operates at the establishment stage, facilitation at the juvenile stage. *d-f*, The population patterns associated with each model. Although these are similar to IFC (Fig. 1), the actual ecological process that the diagrams describe is the outcome of more than simply differences in the life-history characteristics and shade tolerances of the species concerned. 1, Pioneer tree; 2, nursed or late colonizing forest tree; 3, open grown forest tree; vertical axis as in Fig. 1.

ments, nitrogen-fixing herbs, shrubs (for example, *Dryas drummondii*) and small trees (for example, the alders, *Alnus* spp.) occur as pioneers or very early colonizers in successions on basalts in Japan⁸⁷ and glacial moraines in Switzerland, Alaska and Canada⁸⁸⁻⁹⁸. These species must be largely responsible for the marked increases in the amounts of nitrogen and organic matter in the substrates of moraines of increasing age, the factor traditionally assumed to facilitate other species. One exception is the Yukon Territory⁹⁶⁻⁹⁸ where the short growing season is probably the dominant ecological factor.

When it was realized that floristic descriptions of primary successions often resemble IFC^{4,11}, facilitation was then held to have been rejected as an explanation of succession. The crucial point, however, is that the different models of succession are not mutually exclusive. Even where seedlings of forest trees occur in a pioneer environment, both the probability that they will survive and the rate at which they develop to maturity may be increased by continuing autogenic changes. Cooper, for example, is convinced that pioneer spruce (*Picea sitchensis*) at Glacier Bay, Alaska, were permanently stunted and overtopped by later colonizers encountering less extreme conditions⁸⁹⁻⁹¹. Other workers have described symptoms of poor growth, chronic nitrogen deficiency and the probability of high mortality in seedling and juvenile cottonwood (*Populus trichocarpa*), spruce and hemlock (*Tsuga mertensiana* and *Tsuga heterophylla*) on recent moraines⁹²⁻⁹⁴. These observations, however, do not point unambiguously to either holistic model for primary successions, and await explanation. Experimental studies on natural vegetation are clearly required; attention has, however, been drawn by Bradshaw to the possible functional similarities between the environmental changes of primary successions and those brought about artificially through land reclamation work⁹⁹ (although his generalizations about the amounts of nitrogen required in the 'ecosystem' before it will support trees remain to be substantiated). Nitrogen-fixing shrubs and trees are widely used as nurse crops for less robust species while the soil-improving properties of alders have long been appreciated¹⁰⁰. Thus *Alnus sinuata* is recommended as a nurse crop for douglas

fir (*Pseudotsuga menziesii*) on sites low in nitrogen and organic matter¹⁰¹. In New Zealand, a nurse crop of tree lupin (*Lupinus arboreus*) is essential to the establishment of *Pinus radiata* on sand dunes¹⁰².

In conclusion, the generalization that because of the absence of 'competition', early successional environments offer greater levels of resources than do forests, and the corollary that pioneer trees are exploitative and forest species conservative and tolerant of resource shortages, is not supported by the evidence. Often pioneer trees show tolerance, not of shading, but of the extreme temperatures and infertile, often drought-prone substrates of many early successional environments. Forest trees may be tolerant of 'competition', but may well not be tolerant of physically hostile sites. Indeed, there is no reason to suppose that the two types of tolerance are conferred by the same biological attributes. Pioneer trees cause environmental changes which may alleviate constraints on the establishment of forest trees in initially adverse environments. But such a hypothesis and the elements of the reductionistic framework are not mutually exclusive.

The third alternative

The need for a darwinian approach to the analysis of forest succession is beyond dispute. Neither reductionist nor holistic theories of succession have produced models which explain field observations. Yet because the reductionist framework has been described in terms of the Neo-darwinian evolutionary synthesis, it tends to be uncritically accepted. As Gould¹⁰³ has pointed out, the urge to tell (and to believe) a good story affects not only holists.

In essence, the reductionists hold that succession occurs because of the existence of a spectrum of types of life history, which is the basis of the IFC model. Autogenic change is allowed a subsidiary role when its effects are seen as 'negative', as in tolerance and inhibition models. Much importance is also assigned to stochasticism, a disorganizing power as elusive as the emergent properties of the holists¹⁰⁴. The theme of this article has been that the reductionistic story fails, as it stands, for two

reasons: it neglects the nature of seed dispersal, and its generalizations about environmental change and exploitative and conservative species are untenable.

A third, synthetical approach should be sought, if only as a stimulus to further investigations. Life histories and tolerance will be important factors in any model of forest succession, but they cannot be assumed to provide a complete explanation of the phenomenon. In considering which other mechanisms are involved, it is not necessary to view facilitation as inseparable from the other elements of holism, particularly its teleological character. It is in fact adequate to suppose that the fitness of a pioneer tree is dependent only on its ability to colonize, grow and produce seed in early successional environments. The consequent environmental changes and the effect on other species are secondary results of this process. The facilitation model should allow that certain autogenic environmental changes may increase the input of seeds, the establishment of seedlings or the growth and survival of established individuals of forest species. Facilitation, tolerance, inhibition and allogeneses are interdependent mechanisms in succession and may affect the same individual successively or simultaneously during its life cycle (Fig. 4; refs 89–91). The relative importance of the various

mechanisms is likely to vary widely between environments, but attempts to classify succession on the basis of a single underlying mechanism only obscure understanding and inhibit progress.

Reductionism has not solved the succession problem, and will not do so while it relies on the same deduction from inadequate general models which led to the fall of the holistic scheme. For progress, the induction of general theory from fieldwork based in the observational and experimental techniques of plant population biology^{20,21} would seem to have much to recommend it (see ref. 105; unfortunately, not a study concerned with succession). This recalls the problem of time-scale, although many of the problems outlined above could be solved by relatively short-term studies. However, such an approach has the great advantage of theoretical agnosticism and is the least value-laden available. Any other way forward is difficult to see; the general models that have been freely proposed so far are wholly inappropriate in relation to the quality and quantity of available data.

I thank P. J. Grubb, T. A. Rowell, H. J. Harvey, P. Greig-Smith, L. Guarino and J. Mitchley for their interest and time. This work forms part of a study funded by a NERC/CASE research studentship with Thurrock Borough Council.

A model for the evolution of the Grampian tract in the early Caledonides and Appalachians

John F. Dewey* & Robert M. Shackleton†

* Department of Geological Sciences, University of Durham, South Road, Durham DH1 3LE, UK

† Department of Earth Sciences, Open University, Walton Hall, Milton Keynes MK7 6AA, UK

Analogy with models developed for Newfoundland suggests that the ophiolites of the Grampian tract were emplaced as hot, young oceanic crust. The conversion of a mid-ocean ridge-fracture zone system into a subduction zone resulted in the northward emplacement of a giant ophiolite nappe onto the continental margin in the early Ordovician. This obduction occurred long before the collision between the Laurentian and Baltic Shields. The general features of this model may be characteristic of orogens resulting from oceanic closure.

OROGENIC contraction occurs in at least seven ways: (1) above subduction zones at continental margins (Andes); (2) on compressional bends of transform faults (Transverse Ranges); (3) by the compressional collapse of intracontinental extensional zones (Alps); (4) by continent-continent collision (Himalayas); (5) by arc-continent collision (Taiwan); (6) by the collision and lateral displacement of oceanic plateaus and other exotic terranes (North American Cordillera); and (7) by ophiolite obduction (Oman). The earliest interior deformations usually involved ophiolites and blueschist metamorphism, without synchronous flysch or molasse deposition in exterior zones and, therefore, probably occurred below sea level. Collapsed extensional zones have crystalline basement rocks above attenuated subcontinental mantle in the highest nappes, and lack well developed ophiolites. In orogens resulting from the closure of oceans, the highest nappes are ophiolitic, obduction preceding terminal collision

as a distinct event affecting margins. This mechanism was responsible for the evolution of the early Caledonides and is developed here.

The Grampian Orogen

There is now general agreement that the Northern Appalachian/Caledonian orogen evolved by the closing of the Iapetus Ocean¹, with terminal collision in the late Silurian/early Devonian in the Caledonides and in the mid-Devonian in the Northern Appalachians²⁻⁴. The two sides of the orogen have quite different basements, rifting and subduction histories and their only common feature was their 'stitching together' across the Iapetus Suture. The plate tectonic setting of the Grampian tract and its Appalachian equivalents (Fig. 1) has been extensively debated and hypotheses have fallen into three classes: those involving an Andean-type setting above a north-west-

J. Black, personal communication). *r*: 484, Colmonell Gabbro⁶⁷; 478+8, lava; 506+14, basal aureole; 510, metapyroxenite; 476+14, lava; 501+12, lava (Ballantrae Complex). The time scale (in Myr), given in the second column, was generated iteratively from Caledonian/Appalachian data, slightly modifying a time scale given by W. S. McKerrow.

dipping subduction zone, with⁵ or without² ridge-trench interaction; those appealing to collisions between the Laurentian margin and island arcs with southeastward subduction⁶⁻¹¹, or oceanic plateaus¹² with northwestward subduction; and those involving ophiolite obduction either from the south-east¹³⁻¹⁵ or from the north-west¹⁶. The middle part of the Ordovician period was a time of fundamental but diachronous tectonic change throughout the northwestern Appalachian/Caledonian belt from at least Tennessee to Scotland. The Grampian tract underwent its main structural and metamorphic evolution before Llandeilian times in the British Caledonides (Grampian event), before Caradocian times in Newfoundland (Humberian event) and before late Caradocian times in New York and New England (Taconian event) (Fig. 1). The nature of this event is particularly clear in Newfoundland where the Humberian deformation and metamorphism was driven by the progressive early Ordovician northwestward obduction of an ophiolite nappe^{9,15,17-20}. However, in Newfoundland, the post-Humberian tectonic setting is less obvious, whereas in Scotland the reverse is true; the Grampian event is enigmatic and post-Llandeilian northwestward subduction is evident⁴. Any model of the early Caledonides must account for the following features of the Grampian tract: (1) northwestward progression of structural/metamorphic events with the Moine Thrust Zone as the youngest part of the Highland structure; (2) the gross northwestward vergence of the orogen, emphasized by an overall southeastward-younging from the older Moine Series to the younger Dalradian Series; (3) dominant structural vergence to the north-west with the

exception of the Tay (and possibly Banff) Nappe; (4) that the Unst Ophiolite Complex (Fig. 1) is east-facing and structurally overlies the Grampian metamorphic complex.

Outline of the Grampian model

Figure 2 summarizes the facies of the Grampian and adjacent tracts, giving isotopic ages and other data and interpretations that are used as a basis for the model. Figure 3 shows three schematic transects of the orogen.

The Humberian Orogeny in Newfoundland resulted from the destruction of a late Precambrian and Ordovician continental shelf/rise by progressive northwestward obduction of an ophiolite nappe (Bay of Islands Complex), whose obduction timing is well constrained from Arenigian to pre-*Climacograptus bicornis*^{17,20}. This coincided almost precisely with the 30-Myr existence of a calc-alkaline volcanic arc (Notre Dame terrane) to the south-east that grew on a late Tremadocian ophiolite foundation and shows a development from an early Arenigian mafic proto-arc to a more silicic late Arenigian/Llanvirnian mature arc. All well-dated ophiolite complexes in western Newfoundland are of Tremadocian age, that is, they were generated only a few million years before the beginning of their obduction. This suggests that the Humberian Orogeny and the initiation, growth and termination of the Ordovician arc resulted from the nucleation of the initial obduction site on a newly-formed ridge-fracture zone system, southeastward subduction resulting from progressive northwestward obduction and, finally, collision of the arc and obduction of its ophiolite foundation and forearc

Fig. 3 Schematic structural sections (drawn to scale) along lines indicated in Fig. 1. onto the continental margin¹⁸. An Ordovician arc terrane, lying immediately to the south-east of the Grampian tract, occurs intermittently from southern New England to the British Isles (Fig. 1). In Ireland (Fig. 2q), the Ordovician arc shows a mafic to silicic maturation trend, which had begun by mid-Tremadocian times and terminated before the end of the Arenigian. In western New England, arc volcanism continued into early Caradocian times, indicating a diachronous progression of arc development, obduction and collision along-strike towards the south-west. An earliest Llanvirnian intracarbonate disconformity with karsting below and a deepening sequence into shales and easterly derived chromite-bearing turbidites above, is probably the result of flexural loading of the continental margin lithosphere²¹ by the advancing ophiolite sheet; this arching-deepening sequence is younger to the south, being from early to mid-Cardocian age in eastern New York (sub-Chazy/Balmville unconformity).

The contact between the Grampian tract and the arc terrane is a steep zone of ophiolite mélanges and south-east-facing ophiolite slivers (Brompton/Baie Verte/Mings Bight/Clew Bay/Highland Boundary Line^{17,19}), and is interpreted as the suture zone that bounds the Grampian metamorphic complex to the south-east and along which the arc terrane collided with the continental margin^{8,9,17,18}. Within this zone and an immediately adjacent tract comprising the highest Dalradian-Fleur-de-Lys stratigraphy, ophiolite mélanges and ultramafic pods are encased in a matrix of greywacke, black slates and graphitic black schists^{17,22-24} (Killadangan and Achillbeg Complexes). These mélanges are interpreted as a shear carpet formed as ophiolite-derived olistostromes overran and deformed by the northwestward-advancing ophiolite nappe¹⁷. Similar ultramafic pods and slivers occur intermittently within the Grampian Zone in Newfoundland (Pasadena, Coney Head²⁵, Fleur-de-Lys) and in Scotland (Glen Urquhard, Portsoy) and are probably remnant slices of a single supra-Grampian ophiolite sheet tucked into the metamorphics along pinched synclinal slide zones. The Unst Ophiolite Complex is believed to occupy a southeastern root zone position analogous to the Brompton/Clew Bay Zone. The rare occurrences of blueschist in the Grampian Zone are in rocks immediately beneath the proposed ophiolite shear carpet.

Following the development of early Grampian structures with a northwestward vergence, the southeastern part of the Grampian tract and adjacent parts of the Ordovician arc terrane were affected by southward-verging retrocharriage structures following the end of arc volcanism, for example, the D4 Mannin Thrust in Connemara²⁶, the Mings Bight and southeast-verging folds and slide zones of the eastern Burlington Peninsula in New-

foundland, and the rotation of the southern margin of the Tay Nappe into downward-facing attitudes along the Highland Border. In the British Isles, they roughly coincide with the Llandelrian establishment of northward subduction beneath a south-facing arc, along the southern edge of which the Southern Uplands accretionary prism developed. The southeast-verging late Grampian structures may comprise various combinations of shear associated with northward subduction, gravity spreading resulting from D1-D3 crustal thickening and rotation along fault zones at the southern edge of the rising Grampian tract. These southward-verging structures appear to be contemporaneous with, or slightly earlier than, a phase of rapid uplift and denudation of the Grampian tract that began ~460 Myr ago in the British Isles and ~450 Myr ago in Newfoundland and is evidenced by thick clastic sequences (Fig. 2j,p-s) derived from Grampian and Grenville metamorphic sources. The isotopic age pattern of the Dalradian rocks in the British Isles²⁷ indicates a period of rapid uplift, stripping and cooling from 460 to 440 Myr. Uplift was essentially completed by early Silurian times in western Ireland, where Upper Llandoverian strata rest unconformably on the Dalradian (Fig. 2n); uplift was complete by earliest Devonian times south of the Great Glen Fault, where the Lorne lavas lie unconformably on Grampian metamorphics. Of the maximum of ~30 km that was stripped from the Grampian Highlands, 15 km was probably an ophiolite nappe; in Connemara, remnant ultramafic pods at numerous localities along the unconformity between the Dalradian and the Upper Llandoverian suggests the stripping of ~15 km of ophiolite nappe during the mid- and late Ordovician. The Partry Series in the South Mayo Trough is the earliest Grampian molasse and, with earlier Ordovician sediments and volcanics, was folded before the Upper Llandoverian, a phase of shortening which was probably coincident with the mid-Ordovician late D3 to D4 events affecting the Dalradian. Along the southeastern margin of the Grampian Orogen, a short but diachronous lutite lull (Glennamara Slates in western Ireland, *Nemagraptus gracilis*-*C. bicornis* black slates of Newfoundland) immediately followed arc termination and preceded uplift. Thus, we suggest, the final stages of collisional shortening led to a 'flip' in subduction polarity and the beginning of Grampian uplift and denudation.

Grampian ophiolite obduction

All giant ophiolite nappes, including those of Ordovician age in the Appalachian/Caledonian system, are characterized by a very short (<10 Myr) interval between ridge-fracture zone generation and their subsequent obduction detachment^{28,29}, have

Fig. 4 Nucleation of obduction zone on a ridge transform plate boundary and its fracture zone extensions. *a*, Plan of ridge/fracture zone indicating lines of section in *b* and *d* (VX) and *c* and *e* (YZ). TD, transform domain; FZ, polyphase-deformed rocks of transform/fracture zone. *b*, Section across a fracture zone with a contrast between 10 and 20 Myr lithosphere showing detachment of a 15-km-thick ophiolite sheet with a frontal portion of fracture zone rocks. FZ, fracture zone; black areas, mafic rocks; white areas, ultramafic rocks. 1, Brittle; 2, semi-brittle; 3, low-temperature ductile; 4, high-temperature ductile; 5, plastic; 6, low-velocity zone. ■, Range of pressure estimates from basal aureole³⁴; ●, bases of 12-km and 15-km-thick ophiolite sheets. *c*, Section across a ridge showing detachment of an ophiolite sheet along the 950 °C isotherm (solid ■ and ● as in *b*). *d*, True-scale section VX. *e*, True-scale section YZ generated at a half-spreading rate of 2 cm yr⁻¹.

inverted high-temperature metamorphic sole aureoles^{28,29}, initial detachment thicknesses of between 10 and 15 km²⁹, commonly carry primitive calc-alkaline arc volcanics, and may have oceanic fracture zone assemblages along the leading obduction edge^{18,30,31}. This is consistent with the detachment of a slice of oceanic crust and mantle, almost immediately after its generation, along a ductile zone at or near an accreting plate boundary crest or fracture zone, or a combination of both (Fig. 4). The earliest, highest temperature part of the obduction aureole in the Bay of Islands Complex was generated at ~950 °C (refs 32, 33) at the base of a 15-km ophiolite slab, a temperature/depth ratio appropriate for oceanic lithosphere <10 Myr old (Fig. 4c). Ophiolite obduction is easier shortly after generation because the 950 °C potential detachment surface becomes progressively deeper as the lithosphere ages (Fig. 4c). It is less clear what causes ridge → obduction zone conversion. Opening and closing of back and intra-arc basins has been suggested²⁸ but this is unlikely for Grampian ophiolites because they predate immediately volcanic arc development (Fig. 2f-j). Three principal mechanisms seem possible. First, changes in relative motion and intraplate and plate boundary stress patterns may result from regional or global plate boundary reorganization. Obduction by such a cause is likely to be roughly synchronous along great strike lengths of a continental margin, to predate arc development in the region and not to involve substantial syn-obduction rotations.

A second mechanism is related to an evolving trench/transform triple junction such as the Pacific/North American/Farallon junction on the early Tertiary Californian borderland. Flakes

Fig. 5 Central portion of lower hemisphere equal-angle stereographic projections showing two plate boundary geometries that allow a close sequential relationship between ophiolite generation (double line) and beginning of obduction (barbed line). Plates *b* and *c* rotate around poles *ba* and *ac* respectively, which are fixed in the frame of reference of the projection and plate *a*. *bc_i*, The instantaneous rotation pole that describes the relative motion of plates *b* and *c*. ■, Area of plate *c* subducted beneath plate *b* after 60° of rotation of plates *b* and *c* around *ba* and *ac*, respectively; □, area of plates *b* and *c* generated and not subducted, 1-4 represent localities in order of decreasing age at which ophiolite generation is shortly followed by obduction.

of newly-formed ophiolite could continuously transfer to a transform segment that had just been a subduction zone. This obduction mechanism would involve rather small flakes with substantial rotations and would terminate rather than precede volcanic arc activity. A third mechanism results from an inevitable consequence of plate boundary evolution—the progressive change in position of plate boundaries relative to the poles of rotation that describe their relative motion. Where ridge-fracture zone systems pass through or lie close to instantaneous rotation poles, a progressive change from plate divergence to convergence is possible³⁴ (Fig. 5a,b). This mechanism must generate diachronous change from spreading to obduction and is unlikely to cause substantial syn-obduction rotations.

The first and third mechanisms seem likely for large-scale ophiolite obduction, where ophiolite generation generally precedes arc growth. An example of the first mechanism may be the roughly synchronous Neotethyan late Cretaceous obduction from Cyprus to the Himalayas. The progressively later growth and demise of the Ordovician arc along-strike to the south-west within the Appalachian/Caladonian Orogen is best explained by the third mechanism.

Obduction detachment at a fracture zone^{18,30} produces a different configuration from detachment at a ridge crest^{28,29}. Fracture zone obduction (Fig. 4b,d) will involve an ophiolite nappe of approximately uniform across-strike but varying along-strike thickness, with a sheeted dike trend normal to the detachment line. Frontal nappe assemblages will consist of mafic/ultramafic assemblages generated along a fracture zone with complicated polyphase structural and magmatic histories, which form the principal obduction aureole protoliths. Assuming an obduction detachment surface dip of 5° and a converge rate of 2 cm yr⁻¹, the first gabbroic protoliths near the base of the oceanic crust will take 4 Myr to reach the highest aureole temperature and the uppermost oceanic crust will take 8 Myr.

By contrast, ridge crest obduction will generate an ophiolite nappe with approximately constant along-strike thickness, but thinning in the direction of obduction with a sheeted dike trend parallel with the detachment line. Frontal nappe assemblages will consist of newly generated oceanic crust and mantle and will form the earliest obduction aureole protoliths with temperatures as high as 1,200 °C at pressures as low as 2 kbar.

In Newfoundland, the evidence favours ophiolite detachment along a north-east-striking fracture zone (Coastal Complex), a continuation of the dextral transform portion of a long transform/short ridger system approximately parallel with, and a few hundred kilometres from, the early Ordovician continental margin³⁰. The obduction aureole comprises the first stages of a progressive northwestward and downward Arenigian nappe-stacking sequence that culminated with the emplacement of the whole Grampian nappe assemblage onto the platform during the mid-Ordovician. The progressive diminution of aureole temperature and pressure (Fig. 6f) indicates cooling and thinning of the ophiolite sheet during obduction. In a compressional regime, the thinning is unlikely to be tectonic in origin, nor can it have been due to syn-obduction erosion of a planar ophiolite sheet because the highest parts of the oceanic crust are preserved in the Bay of Islands Complex. Also, the earliest stages of thrusting of a 15-km sheet of 10 Myr ophiolite across a 20-Myr oceanic lithosphere would involve wholly submarine obduction with water depths of ~3 km. Even during the earliest stages of late D1/D2 progressive stacking of Dalradian continental margin sediments, shortening was occurring in a zone of thin continental crust and, therefore, emergence would have taken place only when the crust and sediments were restacked to above 30 km¹².

This event is witnessed by the Llanvirnian Crabb Brook³⁵ ophiolitic clastics (Fig. 2e) that rode on the Bay of Islands ophiolite complex. Thinning of the ophiolite nappe was probably mainly due to D3 buckling and erosional stripping, accounting for steeply dipping complete ophiolite sections transected by the final obduction thrust (Fig. 6d). During this early Arenigian early obduction phase, the obduction aureole and the highest Dalradian rocks in ophiolitic wildflysch sequences, such as those of Clew Bay³⁶, assume great significance because they probably record a direct relationship between structure and fabric and the obduction slip direction, which in turn is likely to be, more or less, the direction of relative motion of the plate. The aureole, in particular, will record the very earliest convergence slip direction following and perhaps progressively changing from the ridge transform direction, which will be preserved in the frontal portion of the ophiolite sheet and, more obscurely, in ophiolitic blocks in the highest wildflysch. Complicated structural sequences in mafic protoliths in metamorphic belts with younger structural sequences must be viewed, therefore, with extreme caution; they may represent obducted fracture zone rocks and not portions of an older crystalline basement. Systematic studies of early obduction structures have not been undertaken and are of paramount importance in attempts to relate structural geology to plate tectonics.

As D3 shortening progressed, the regional plane strain that had characterized D1 and D2 led to a progressive loss of the relationship between slip vector and fabric and to more complicated regional strains, partly driven by body forces involving flaking, wedging and rotation, with axial extensions and consequent strike-slip motions in a locally 70 km-thick crust. D3 shortening, with complexities probably partly due to the irregularities of the Laurentian rifted margin, choked the obduction zone, terminated the arc and led to D4 rotation²⁶ and retrocharriage and to northward subduction beneath, and uplift of, the Grampian tract (Fig. 6d,e). Mafic intrusions occur in several parts of the Grampian tract (Cashel Suite in Connemara, Newer Gabbros in Scotland) and predate D3. If they are the roots of arc volcanics³⁷, this model is invalidate, at least for the British Isles, because they would imply northward subduction during the Arenigian. They may, however, have been

Fig. 6 a-e, Approximately true-scale schematic sections to account for the Grampian Orogeny, illustrating the progressive obduction of an ophiolite sheet across, and the sequential stacking of, a continental rise and continental shelf, the shortening and thickening of the continental margin rocks and the consequent flip in subduction polarity; for symbols see Fig. 3. f, Pressure-temperature plot of rocks of the basal aureole³². developed in strike-slip pull-aparts or by delamination of the lithosphere³⁸ during shortening.

Displaced terranes and the closure of Iapetus

The Bay of Islands fracture zone model³⁰ implies a right-lateral component of Tremadocian/Arenigian relative plate motion across the Grampian Zone. Post-Llandeilian relative motion, however, until the late Silurian to mid-Devonian diachronous closure of Iapetus, involved a substantial component of left-lateral displacement. Very large sinistral late Devonian-Carboniferous displacements have been suggested^{39,40} to have occurred along the Appalachian/Caledonian chain, but the geological evidence clearly shows Carboniferous motion to have been right-lateral^{12,41}. We believe that all sinistral motion occurred between Caradocian and mid-Devonian times, based on the following evidence. The Great Glen/Leannan Fault and other roughly parallel faults moved during the early Devonian⁴² and probably have a total cumulative offset of a few hundred kilometres. Extensional bends in associated shear zones were critical in controlling the emplacement of granite plutons⁴³. The Highland Boundary Fault truncates the Dalradian terrane and juxtaposes it with the Midland Valley, which appears to consist of a Grenville basement stretched and underplated by a mafic lower crust during the latest Precambrian (B. J. Upton, personal communication) with superposed early Ordovician ophiolite obduction, a terrane very similar to the Long Range of southwest Newfoundland. Their original contiguity implies a sinistral displacement of at least 1,000 km which probably occurred from late Silurian to the end of the early Devonian, giving a slip rate of ~5 cm yr⁻¹. This large sinistral motion would account for the entrainment of a wide variety of Ordovician and Silurian rocks along the Highland Border⁴⁴. This further implies that the clastic source of the Southern Uplands accretionary prism, which must have travelled at least as far as the Midland Valley, cannot have been the Scottish Highlands, a notion supported by the fact that the Lower Devonian rocks of the Midland Valley have a source other than the Scottish Highlands⁴⁵.

In western Ireland, the Dalradian rocks of Connemara are in an anomalous position to the south of the Clew Bay Ophiolite Zone and the Ordovician volcanic rocks of the South Mayo Trough^{46,47}. The latter cannot have been thrust across the

Dalradian because their very preservation means that they escaped the large uplifts and denudations (>15 km) suffered by the Grampian metamorphics and hence cannot be underlain by Dalradian rocks. Upper Llandoveryan strata rest unconformably across a concealed contact between the Ordovician rocks of the South Mayo Trough and the Connemara Dalradian where the Lough Nafuoey Fault Zone was a major controlling influence on Arenigian volcanism and sedimentation⁴⁸. This fault zone is interpreted here as a major post-Llandeilian, pre-Upper Llandoveryan strike-slip fault along which Connemara was displaced from the set by ~500 km. Lastly, early Devonian terminal closure of Iapetus in north-central Newfoundland had a strong sinistral component as evidenced by sets of sinistral Riedel faults in New World Island between the Lukes Arm and Reach Faults. The sum of all these post-Grampian sinistral motions is at least 1,800 km and had the effect of severely modifying, by strike-slip omission and repetition, the Grampian tract and its post-Llandeilian subduction-accretion neighbouring terrane to the south, and may have been responsible also for substantial pre-collisional modification to the southern margin of Iapetus such as the truncation of the Lake District forearc region⁴⁹. Perhaps the northern margin of Iapetus between Llandeilian and late Silurian times was similar to the Mesozoic-Cenozoic western margin of North America where complex plate interactions were driven by roughly strike/slip motion between the large plates.

Conclusions

The pre-Grampian margin of the Laurentian Shield in the Appalachians was a continental shelf-rise generated by latest Precambrian continental separation. Continental separation was heralded by the eruption of the Tayvallich and Lighthouse Cove mafic lavas. The Dalradian rocks were evidently laid down in a basin bounded to the south by a horst³. The pre-Grampian right-lateral phase of offshore ridge/transform tectonics may have been responsible for the removal of this crystalline horst (perhaps now the basement of the Ammonoosuc Zone in western New England), much as the opening of the Gulf of California is transporting a narrow Baja continental sliver northwards to open up the transform continental borderland of Mexico. The offshore ridge/transform boundary was converted, almost immediately and probably diachronously, along the length of the Appalachian/Caledonian Orogen, into an obduction zone during Tremadocian-early Arenigian times. It was the progressive northward obduction of a 15-km ophiolite sheet that stacked a subadjacent Dalradian nappe pile, to the south of which grew an Arenigian volcanic arc on a Tremadocian ophiolite foundation. Grampian crustal shortening was below sea level for a substantial part of the early Ordovician until rapid D3 shortening and crustal thickening led to a flip in subduction polarity, the beginning of southward-verging subduction accretion and rapid uplift and stripping of the Grampian tract. The ophiolite nappe is preserved in the steep suture zone between the arc and the Dalradian terrane and where it reached the platform. In the uplifted and denuded axial part of the Grampian Zone, it is preserved only in high-level slide zones in lower grade regions.

The obduction model proposed here may be a template for the evolution of most Barrovian mountain belts of Grampian type that evolve prior to terminal oceanic closure. Major ophiolite obduction seems to occur long before continental collision and emphasizes the observation of Hess⁵⁰ that the great Alpine-type ultramafic belts were generated during the first major deformational events in the mountain belt that contains them. This massive scale of obduction appears to result from ridge-fracture zone → obduction zone conversion and may be significant with regard to global plate tectonics. As in the early Ordovician, a similar period of widespread obduction occurred in mid- and late Cretaceous times and was also temporally coincident with blueschists, arc activity, seamount-continental margin collision, continental margin orogeny and widespread platform carbonate signalling a high sea level and rapid subduction¹².

The post-Grampian sinistral motion of almost 1,800 km has

implications for the relationship between the Grampian margin of the Laurentian Shield, the Avalonian terrane and the Baltic Shield (Fig. 1). If this relative motion were carried along-strike between Greenland and Scandinavia, it would imply that the south-east-verging Scandinavian Caledonides were opposite Newfoundland and Ireland in immediately post-Grampian times. As a more plausible explanation, we suggest that a major oceanic triple-junction complex existed in the North Sea⁵¹ between the Scandinavian, British and North German Caledonides and that subduction along the latter absorbed a large part of the Avalonian-Laurentian relative motion. Considerable differences exist between the Grampian tract in the Appalachians and Caledonides. In the Appalachians, a narrow zone of Grampian thrusting and ophiolite obduction was completed by mid-Ordovician times and the Connemara Dalradian was stripped by late Llandoveryan times. In Scotland, the Grampian Zone is wider and thrusting continued into the Silurian in the Moine terrane⁴². A possible explanation is that a D4 subduction polarity change following D1-D3 obduction was followed shortly by Silurian continental collision between the Laurentian and Baltic Shields and by progressive oceanic closure, with a strong sinistral component, culminating in late Silurian to mid-Devonian collision between Avalonia and a semi-consolidated Laurentian/Baltic continent. This collision induced Devonian sinistral strike-slip between the Laurentian and Baltic Shields (Great Glen phase). Before terminal closure of Iapetus, major strike-slip faulting occurred along the Grampian borderland of Laurentia. Of the 1,800 km of Avalonia-Laurentia relative motion, about 500 km was absorbed by late Silurian-early Devonian shortening in the North German/Polish Caledonides, and the remainder accounted for the Devonian left-lateral displacement of Scandinavia relative to Laurentia.

We acknowledge discussions with D. H. W. Hutton and N. J. Soper, who in complementary work have reached similar conclusions about separate Laurentian-Baltic and Laurentian-Avalonian collisions. We thank W. S. McKerrow and H. Williams for critical reviews.

Cloning and sequence analysis of cDNA for the Electrophorus electricus electroplax sodium channel indicate that this protein, consisting of 1,820 amino acid residues, exhibits four repeated homology units, which are presumably oriented in a pseudosymmetric fashion across the membrane. Each homology unit contains a unique segment with clustered positively charged residues, which may be involved in the gating structure, possibly in conjunction with negatively charged residues clustered elsewhere.

THE sodium channel is a membrane protein that mediates the voltage-dependent modulation of the sodium ion permeability of electrically excitable membranes^{1,2}. The ionic basis for the generation of action potentials has been well understood³. The initial increase and subsequent decrease in sodium ion permeability during an action potential implies that the sodium channel can exhibit at least three distinct functional states: resting (closed), activated (open) and inactivated (closed). A variety of pharmacological agents, including neurotoxins, affect the complex function of the sodium channel⁴. The use of binding assays based on the high specificity of such neurotoxins has permitted purification of the sodium channel from the electric organ of the eel *Electrophorus electricus*⁵⁻⁷ as well as from rat brain⁸, rat skeletal muscle⁹ and chick cardiac muscle¹⁰. It has been reported that the *Electrophorus* sodium channel⁷ and its avian counterpart¹⁰ consist of a single polypeptide of molecular weights 260,000-300,000 and 230,000-270,000, respectively, whereas its mammalian counterparts^{8,9} contain, in addition to the corresponding large polypeptide, two or three smaller polypeptides of molecular weights 37,000-45,000. The purified eel and rat sodium channel preparations have been shown to be functional when reconstituted into phospholipid vesicles¹¹⁻¹⁴.

To understand the molecular mechanisms underlying the selective ion transport and voltage-dependent gating operated by the sodium channel, it is essential to elucidate the primary structure of the constituent protein. Using recombinant DNA techniques, we have now cloned DNA sequences complementary to the messenger RNA coding for the sodium channel protein of *El. electricus* electroplax. Nucleotide sequence analysis of the cloned cDNA has revealed the complete amino acid sequence of this polypeptide.

Partial amino acid sequence

The initial approach used to clone cDNA sequences for the sodium channel protein was to combine immunological screening of a cDNA expression library with identification of the

isolated clones by comparison with the partial amino acid sequences determined by peptide analysis. The sodium channel protein from *El. electricus* electroplax was solubilized with Lubrol-PX and purified by chromatography on DEAE-Sephadex and gel filtration on Sepharose 6B (refs 5, 6), followed by gel filtration on Sepharose 4B in denaturing conditions⁷ and gel permeation HPLC (see Fig. 1 legend). This procedure yielded a homogeneous preparation (Fig. 1A). The purified protein was digested with trypsin, and the resulting peptides were fractionated by reverse-phase HPLC (Fig. 1B). After rechromatography (Fig. 1C), five peptide fractions (fractions Ib, IIa, IIb, IVa and Vb) were isolated and analysed for amino acid sequence with the use of a gas-phase sequencer¹⁵. Six peptide sequences were thus determined (Fig. 1D); fraction Ib proved to contain two peptides. Attempts to determine the amino-terminal sequence of the whole sodium channel protein by Edman degradation were unsuccessful.

Isolation of cDNA clones

A library of cDNA clones was constructed with poly(A)-containing RNA from *El. electricus* electroplax as template and the plasmid expression vector pUC8 (refs 16, 17). Screening of the cDNA library¹⁷ with rabbit antiserum to the purified *El. electricus* sodium channel protein yielded four immunologically positive clones from $\sim 8 \times 10^4$ transformants. Plasmid DNA was isolated from the four clones, and the cDNA insert of each clone was subjected to blot hybridization analysis¹⁸ with a synthetic oligodeoxyribonucleotide probe containing all possible cDNA sequences predicted from the partial amino acid sequence Thr-Phe-Phe-Glu-Pro of the tryptic peptide Vb (see Fig. 1D, e); the third position of the proline codon was not included. Only one of the four clones, pSCH1 (see Fig. 2), carried a hybridization-positive cDNA insert. Nucleotide sequence analysis¹⁹ of this cDNA insert revealed that clone pSCH1 contained a 426-base pair (bp) cDNA insert including the coding sequence for the whole known amino acid sequence

Fig. 1 Purification and partial amino acid sequence analysis of the *El. electricus* sodium channel protein. **A**, Electrophoretic analysis of the purified protein on an SDS-6% polyacrylamide gel¹³. The size markers used were chicken ovalbumin [molecular weight (M_r), 45,000 (45K)], bovine serum albumin (M_r , 68K), rabbit muscle phosphorylase *b* (M_r , 93K), *Escherichia coli* β -galactosidase (M_r , 116K) and rabbit myosin heavy chain (M_r , 200K); bromophenol blue served as tracking dye. The polypeptides were stained with Coomassie brilliant blue. **B**, Reverse-phase HPLC of tryptic peptides. The tryptic digest was directly loaded onto a Chemcosorb 3 μ C₁₈-H column (8 $\times$ 75 mm; Chemco) equilibrated with 0.1% trifluoroacetic acid, and a linear gradient of 0–60% acetonitrile was applied over 80 min at a flow rate of 2 ml min⁻¹; a Hitachi 635 HPLC system with a solvent programmer was used. The eluate absorbance at 210 nm was recorded with a Hitachi 41 UV monitor. Five fractions (I–V) corresponding to absorbance peaks were collected. **C**, Second reverse-phase HPLC. Fractions I, II, III, IV and V (**a**, **b**, **c**, **d** and **e**, respectively) were further purified by reverse-phase HPLC on a Novapak 5 μ C₁₈ column (3.9 $\times$ 150 mm; Waters). The column was equilibrated with 0.1% ammonium acetate buffer, pH 6.0 (**a**), 0.1% ammonium acetate buffer, pH 6.0, containing 10% acetonitrile (**b**) or 10 mM ammonium formate buffer, pH 4.0, containing 10% acetonitrile (**c–e**), and a linear gradient of 0–60% (**a**), 10–60% (**b**) or 10–50% acetonitrile (**c–e**) over 60 min was used at a flow rate of 1 ml min⁻¹. Peak fractions (Ib, IIa, IIIb, IVa and Vb) were collected. **D**, Sequence analysis of peptides. Fractions Ib (**a**), IIa (**b**), IIIb (**c**), IVa (**d**) and Vb (**e**) were subjected to amino acid sequence analysis with a gas-phase sequencer¹⁵ (model 470A, Applied Biosystems). Phenylthiohydantoin (PTH)-amino acids were analysed by HPLC at 50 °C using an Ultrasphere ODS column (4.6 $\times$ 250 mm; Altex) with a three-solvent gradient (acetonitrile, water and 40 mM sodium acetate buffer, pH 5.6) at a flow rate of 1 ml min⁻¹. The yield of PTH-amino acids at each cycle of Edman degradation is shown; the one-letter amino acid notation is used. Fraction Ib was a mixture of two peptides, whose sequences were assigned as indicated, assuming that glutamine is shared by the two peptides at the fifth amino acid position.

Methods: Approximately 2 mg of the partially purified sodium channel protein (Sephacose 6B fraction^{5,6}), derived from about 200 g of *El. electricus* electric organ (World Wide Scientific Animals), was further purified by gel filtration on Sepharose 4B in denaturing conditions⁷. Fractions enriched in sodium channel protein (derived from ~600 g of electric organ) were combined and alkylated at 25 °C for 30 min with 0.1 M iodoacetamide in the presence of 0.13 M 2-mercaptoethanol, 0.1% SDS and 0.4 M Tris-HCl buffer, pH 8.0. After desalting with a Biogel P-100 column (1.5 $\times$ 20 cm) equilibrated with 0.02% SDS, the sodium channel protein was finally purified by gel permeation HPLC on a TSK 4000 column (7 $\times$ 600 mm; Toyo Soda) using 50 mM sodium phosphate buffer, pH 7.5, containing 0.1% SDS at a flow rate of 0.5 ml min⁻¹; the yield was ~300 μ g. The purified material was dialysed against water, lyophilized and dissolved in 90 μ l of 0.1 M ammonium bicarbonate containing 10 mM CaCl₂. TPCK-treated trypsin (Worthington) was added at a sodium channel protein/trypsin ratio of 100. After incubation at 37 °C for 12 h, a further identical aliquot of TPCK-treated trypsin was added, and the incubation was continued for additional 12 h.

of the tryptic peptide Vb. When total RNA from *El. electricus* electroplax was subjected to blot hybridization analysis²⁰ with the cDNA insert of each of the four clones as probe, an RNA species of ~8,000 nucleotides was hybridizable not only with clone pSCH1 but also with another clone, pSCH4 (see Figs 2, 4); no hybridizable RNA was detected with the two remaining clones. This suggested that both pSCH1 and pSCH4 carried a cDNA sequence for the sodium channel protein.

To clone longer cDNA sequences, we next constructed a cDNA library, using poly(A)⁺ RNA from *El. electricus* electroplax and the plasmid vector elaborated by Okayama and Berg²¹. Screening of this library²² by hybridization with the combined cDNA inserts of clones pSCH1 and pSCH4 yielded 14 hybridization-positive clones from ~2 $\times$ 10⁵ transformants. All 14 clones

hybridized with the pSCH1 probe, whereas only 6 of them hybridized with the pSCH4 probe. Clone pSCH14, which apparently harboured the largest cDNA insert among the 14 clones, contained the whole cDNA sequence carried by pSCH1, but did not extend to the 5' end of the cDNA carried by pSCH4 (see Fig. 2). Therefore, additional ~1 $\times$ 10⁶ transformants from the same Okayama-Berg library were screened with a hybridization probe derived from the 5'-terminal portion of the cDNA insert of pSCH4. Thus, five hybridization-positive clones were isolated. One of these clones, pSCH50, which apparently contained the largest cDNA insert among them, extended beyond the 5' end of the cDNA insert of pSCH4 (see Fig. 2).

Because clone pSCH50 apparently did not carry the entire protein-coding sequence, however, additional clones harbouring

Fig. 2 Strategy for sequencing cloned cDNA encoding the *EL electricus* sodium channel protein. The restriction map displays only relevant restriction endonuclease sites, identified by numbers indicating the 5'-terminal nucleotide generated by cleavage (for the nucleotide numbers, see Fig. 3). The poly(dA)·poly(dT) tract and the poly(dG)·poly(dC) tails are not included in the restriction map. The protein-coding region is indicated by a closed box, the sequence used for specific priming of reverse transcription by a small open box and the sequences used as hybridization probes for selecting clones by hatched boxes. The direction and extent of sequence determinations are shown by horizontal arrows under each clone used; the sites of 5'-end labelling are indicated by short vertical lines at the end of arrows. The slash marks at the end of arrows mean that the site of 5'-end labelling was located on the vector DNA^{21,46,47} (*Hpa*II, *Pst*I or *Pvu*II), on the linker DNA (*Eco*RI or *Sal*I) or at the boundary between the 3'-non-coding sequence and the poly(dA)·poly(dT) tract (*Aha*III) as follows: *Eco*RI (left marks) and *Sal*I (right marks) for pSCH1 and pSCH4; *Aha*III (upper right mark) and *Pvu*II (lower right mark) for pSCH14; *Pst*I (left mark) and *Pvu*II (right mark) for pSCH50; *Pst*I for pSCH331 and pSCH377; *Hpa*II for pSCH411.

Methods: Total RNA was extracted⁴⁸ from *EL electricus* electric organs, and poly(A)⁺ RNA was isolated by oligo(dT)-cellulose chromatography⁴⁹. The procedures used for the construction of the cDNA expression library and for the immunological screening of transformants were essentially the same as described by Helfman *et al.*¹⁷. Using 15 µg of poly(A)⁺ RNA, we obtained 500 ng of cDNA, whose internal *Eco*RI sites were blocked by methylation. The cDNA library constructed by ligation to *Eco*RI/*Sal*I-cut pUC8 plasmid¹⁶ gave ~3,000 ampicillin-resistant transformants per nanogram of cDNA when the efficiency of transformation with supercoiled pUC8 DNA was 3×10^4 ng⁻¹. The library transformed to *E. coli* DH1 (ref. 50) and plated on nitrocellulose filters was screened by incubating the filters first with rabbit antiserum to the purified *EL electricus* sodium channel protein⁵¹ and then with ¹²⁵I-protein A (NEN); the antiserum had been preabsorbed at 4 °C for 5 h with a sonicated lysate prepared from the parental bacterial strain DH1, which carried pUC8 plasmid. The oligodeoxyribonucleotide probe used for testing the four immunologically positive clones was a mixture of 32 tetradecaners, 5'-GGTCAAGAAAGT-3', synthesized⁵² as two pools containing A/T or G/C at the twelfth position, where N denotes a mixture of A, T, G and C. The blot hybridization was carried out by the procedure of Southern¹⁸ with the probe labelled with ³²P at the 5' end. RNA blot hybridization analysis was performed by the procedure of Thomas²⁰. Clones pSCH1 and pSCH4 were thus isolated. For the isolation of clones pSCH14 and pSCH50, a cDNA library was constructed by the method of Okayama and Berg²¹, using 10.2 µg of poly(A)⁺ RNA and 4.2 µg of the vector-primer DNA. *E. coli* HB101 (ref. 53) was used for transformation⁵⁴, and ampicillin-resistant transformants were screened²² by hybridization at 60 °C with the following DNA fragments: all hybridization probes were labelled by nick-translation⁵⁵ with [α -³²P]dCTP unless otherwise stated. The first screening was carried out with an equimolar mixture of the *Eco*RI/*Sal*I-excised cDNA inserts of pSCH1 and pSCH4, which carried residues 4,716–5,141 and residues 2,703–4,674, respectively, and the second screening with the 257-bp fragment (excised from pSCH4) extending from the *Eco*RI site flanking the cDNA insert to the *Bgl*II (2,952) site. For the isolation of clones pSCH331, pSCH377 and pSCH411, the synthetic oligodeoxyribonucleotide primer 5'-CATGCTTCGTGATC-3', complementary to residues 2,872–2,885, was elongated by reverse transcription of the mRNA. Single-stranded cDNA was synthesized using 1 nmol of this primer and 200 µg of electroplax poly(A)⁺ RNA (denatured by methylmercuric hydroxide) as template and was converted to double-stranded cDNA, which was cloned in pBR322 plasmid by inserting it into the *Pst*I site using poly(dG)·poly(dC) homopolymeric extensions; the procedures used were as described previously⁵⁶. In the first screening, ~1,000 hybridization-positive colonies were obtained from ~1 × 10⁶ tetracycline-resistant transformants, using the *Hinf*I (1,786)–*Bgl*II (2,160) fragment derived from pSCH50 as probe. Forty-eight clones, selected randomly, were isolated, and clone pSCH331 harboured the longest cDNA insert among them. In the second screening, 65 hybridization-positive colonies were obtained from ~5 × 10⁵ transformants, using the *Rsa*I (103)–*Rsa*I (308) fragment derived from pSCH331 as probe. Among the 24 clones selected randomly, clone pSCH377 carried a cDNA insert extending most upstream. In the third screening, where the filters used in the second screening were re-used, 25 additional hybridization-positive clones were isolated, using the *Rsa*I (–235)–*Hinf*I (–37) fragment derived from pSCH377 as probe. Among them, clone pSCH411 carried a cDNA insert extending most upstream.

cDNA sequences for a region further upstream were isolated as follows. A specific oligodeoxyribonucleotide primer corresponding to a sequence found near the 5' end of the cDNA insert of clone pSCH4 was elongated by reverse transcription of the mRNA, and the resulting cDNA transcripts were cloned into the plasmid pBR322 and screened by hybridization with appropriate restriction fragments derived from cDNA clones isolated earlier. Thus, clones pSCH331, pSCH377 and pSCH411, whose cDNA inserts all extended beyond the translational initiation site, were obtained (see Fig. 2).

Nucleotide sequence analysis of the cDNA clones was carried out by the procedure of Maxam and Gilbert¹⁹ according to the strategy indicated in Fig. 2. Experimental details for the isolation of the cDNA clones are given in Fig. 2 legend.

cDNA and protein sequences

Figure 3 shows the 7,230-nucleotide sequence (excluding the poly(dA) tract) of the cDNA encoding the *EL electricus* sodium channel protein, determined using clones pSCH1, pSCH4, pSCH14, pSCH50, pSCH331, pSCH377 and pSCH411. No nucleotide difference was observed among the cDNA sequences determined with the individual clones, except that the polyadenylation site differed by four nucleotides between clones pSCH14 and pSCH50 (see below). All of the six partial amino acid sequences determined by peptide analysis (see Fig. 1D) were found to be encoded by the cDNA sequence in the same reading frame (amino acid residues 420–425, 432–441, 861–872, 1,596–1,611, 1,677–1,691 and 1,774–1,781). By using this reading

Fig. 3 Nucleotide sequence of cloned cDNA encoding the *EL electricus* sodium channel protein. The nucleotide sequence was determined with clones pSCH1, pSCH4, pSCH14, pSCH50, pSCH331, pSCH377 and pSCH411. Nucleotide residues are numbered in the 5' to 3' direction, beginning with the first residue of the ATG triplet encoding the initiative methionine, and the nucleotides on the 5' side of residue 1 are indicated by negative numbers; the number of the nucleotide residue at the right end of each line is given. The deduced amino acid sequence of the sodium channel protein is shown above the nucleotide sequence, and amino acid residues are numbered beginning with the initiative methionine. Residue 6,846 in the cDNA insert of clone pSCH14 and residue 6,842 in that of clone pSCH50 are followed by a poly(dA) tract, which is connected with the vector DNA sequence.^{21,47}

Fig. 4 Autoradiogram of blot hybridization analysis of *El. electricus* electroplax RNA with a cDNA probe. Total RNA (20 µg) was analysed by the procedure of Thomas²⁰. The hybridization probe used was the *Ava*II (193)–*Ava*II (1,675) fragment derived from clone pSCH411. The size markers used were calf and *E. coli* rRNA⁵⁷. Blot hybridization with other probes derived from different regions of the cloned cDNA exhibited a single hybridization-positive band with the same size; the probes used were the 577-bp fragment (excised from clone pSCH411) extending from the *Ava*II site flanking the cDNA insert to the *Ava*II (193) site, the *Ava*II (1,861)–*Hinc*II (2,422) fragment derived from clone pSCH411, the *Eco*RI/*Sal*I-excised cDNA insert of clone pSCH4 (carrying residues 2,703–4,674) and that of clone pSCH1 (carrying residues 4,716–5,141).

frame, the amino acid sequence of the cryptic portion of the sodium channel protein was deduced (Fig. 3). The translational initiation site was assigned to the methionine codon composed of nucleotide residues 1–3 because this is the first ATG triplet that appears downstream of the nonsense codon TAG (residues –42 to –40) found in-frame. This assignment is supported by the fact that the sequence surrounding the ATG triplet agrees with the favoured sequence that flanks functional initiation codons in eukaryotic mRNAs²³, that is, $\hat{A}XXAUGG$, where X can be any nucleotide; the sequences flanking the following 13 methionine codons do not match this favoured sequence. Reverse transcriptase-mediated elongation of the *Hind*III (–250)–*Hinc*II (–307) fragment derived from the 5'-terminal region of clone pSCH411 yielded a cDNA transcript of ~600 nucleotides, suggesting that no more than ~500 nucleotides are missing from the cDNA we have cloned. This is consistent with the size of the mRNA coding for the sodium channel protein (~8,000 nucleotides) as estimated by blot hybridization analysis²⁰ of electroplax RNA (Fig. 4). The codon specifying the valine residue at position 1,820 is followed by the translational termination codon TAA. The length of the 3'-non-coding region of the cDNA is 1,386 nucleotides (clone pSCH14) or 1,382 nucleotides (clone pSCH50), excluding the poly(dA) tract. Two overlapping copies of the polyadenylation signal²⁴ AATAAA (residues 6,831–6,836 and 6,827–6,832) are found 16 nucleotides upstream from the poly(dA) tract of the respective clones.

From the cDNA sequence, we conclude that the *El. electricus* sodium channel protein is composed of 1,820 amino acid residues. The molecular weight of the protein is calculated to be 208,321. This value agrees with the reported molecular weight of the protein moiety of the sodium channel protein, whose carbohydrate content is ~29% by weight⁷. The amino acid composition of the sodium channel protein predicted from the cDNA sequence compares reasonably well with that determined⁷. There are 10 potential sites of N-glycosylation²⁵, that is, Asn-X-Ser/Thr, where X can be any amino acid except proline²⁶ (asparagine residues at positions 205, 278, 288, 317, 591, 690, 797, 1,160, 1,174 and 1,806); six of them are assigned to the extracellular side of the membrane (see below).

The protein structure

Homology matrix comparison²⁷ of the amino acid sequence of the sodium channel protein reveals the presence of four internal repeats that exhibit sequence homology. Figure 5 shows the alignment of the amino acid sequences of the four repeats, which consist of residues 111–419 including a non-homologous seg-

ment of residues 285–342 (repeat I), residues 555–807 (repeat II), residues 989–1,281 including a non-homologous segment of residues 1,172–1,194 (repeat III) and residues 1,311–1,587 including a non-homologous segment of residues 1,490–1,505 (repeat IV). Of the positions aligned, 54%, 54%, 43%, 50%, 54% and 47% are occupied by identical residues or residues considered to be favoured substitutions for the I/II, I/III, I/IV, II/III, II/IV and III/IV pairs, respectively; the non-homologous segments have not been included in the calculation, and gaps have been counted as one substitution regardless of their length. Statistical tests²⁷ show that the sequence similarity among the four repeats is highly significant, except for the I/IV pair, the probability of occurrence by chance being less than 10^{-9} for the I/II, I/III, II/III and II/IV pairs and 1.3×10^{-3} for the III/IV pair. This observation strongly suggests that the four repeated homology units of the sodium channel protein have evolved from a single common ancestor by internal duplications.

The amino acid sequence of the sodium channel protein was analysed for predicted secondary structure²⁸ and for local hydrophathy²⁹ (Fig. 6A). The segments that can form structures of α -helix or β -sheet extend over a wide range of the protein molecule. The hydrophathy profile along the polypeptide chain indicates that each repetitive homology unit contains five hydrophobic segments (S1, S2, S3, S5 and S6) at equivalent positions. In addition, each unit contains a characteristic segment with strong positive charge (S4) located between segments S3 and S5.

Segments S5 and S6 in each repeat correspond to highly hydrophobic regions with predicted secondary structure that comprise a continuous stretch of 24–38 uncharged amino acid residues including many nonpolar residues. These hydrophobic regions are flanked on both sides by charged residues. Because such a sequence is characteristic of transmembrane protein segments, segments S5 and S6 most probably traverse the membrane, forming α -helical structures^{30–32}.

Segments S1, S2 and S3 in each repeat represent hydrophobic regions with predicted secondary structure consisting of 18–28 amino acid residues that are largely nonpolar but include a few charged residues. Negatively charged residues predominate in segments S1 and S3, whereas both positively charged and negatively charged residues are present in segment S2, so that this segment generally has no net charge. If an α -helical structure is assumed for these segments, the charged side chains in them are clustered largely on one side of the helix, the opposite side being occupied mostly by nonpolar side chains. Thus, segments S1, S2 and S3 can also span the membrane, forming amphipathic α -helical structures.

Segment S4 in each repeat represents a positively charged region with predicted secondary structure comprising 21 amino acid residues including five to seven arginine or lysine residues; arginine residues predominate. This segment exhibits a unique structural feature in that the arginine or lysine residues are located at every third position. The residues intervening between these basic residues are mostly nonpolar. If an α -helical structure is assumed for this segment, the positively charged side chains would be distributed along a spiral line, making a three-quarter to one turn. Alternatively, if a 3_{10} -helical structure is assumed, they would lie on one side of the helix so that the segment would be strongly amphipathic. On the other hand, if a β -sheet structure is assumed, they would extend alternately towards both sides of the peptide backbone.

It seems reasonable to postulate that the four repeated homology units are oriented in a pseudosymmetric fashion across the membrane. If this is the case, each unit should contain an even number of transmembrane segments because no additional hydrophobic segments are predicted outside the homology units (see Fig. 6A). The transmembrane segments are most likely to be involved directly or indirectly in the formation of the ionic channel. As the minimum cross-section of the channel is considered to be $3 \times 5 \text{ \AA}$ (refs 33, 34), at least one helical segment from each repetitive unit would take part in constructing the inner wall of the ionic channel at the narrowest point. The remaining helical segments may surround those forming the

Fig. 5 Alignment of the amino acid sequences of the four internal homology units. The sequences of repeats I (top), II (second row), III (third row) and IV (bottom) are aligned. The one-letter amino acid notation is used, and the numbers of the residues on each line are given on the right side. Identities or favoured amino acid substitutions among three or four residues at one aligned position are indicated by boxes. Favoured amino acid substitutions are defined as pairs of residues belonging to one of the following groups: S, T, P, A and G; N, D, E and Q; H, R and K; M, I, L and V; F, Y and W (ref. 58). Gaps (-) have been inserted to achieve maximum homology. The non-homologous segments in repeats I, III and IV are shown by lines; the sum of residues present in each non-homologous segment is given in parentheses. Segments S1-S6 are indicated.

channel, or some of them may face the channel in its dilated portion. In view of the strong hydrophobicity and the uncharged nature of segments S5 and S6, there seems to be little doubt that they represent transmembrane segments. It is likely that two of the three segments S1, S2 and S3 also traverse the membrane. The negatively charged side chains in segment S1 and/or segment S3 may be related to the ion selectivity of the sodium channel³⁵. The presence of a continuous stretch of 31 uncharged residues in the S1 region of homologous repeat I seems to favour the view that segment S1, together with segment S2 (or S3), spans the membrane.

The sodium channel protein, in contrast to many other transmembrane proteins³⁶, does not possess an amino-terminal sequence characteristic of the signal peptide³⁷. There are a number of such precedents³⁸⁻⁴¹, and transmembrane proteins devoid of a cleavable signal peptide are considered to have their amino terminus on the cytoplasmic side of the membrane³¹, as this is in fact the case for the erythrocyte anion transport protein band III (ref. 38). On the basis of the considerations mentioned above, the transmembrane topology of the sodium channel protein molecule has tentatively been assigned as shown in Fig. 6B. The possibility that segment S3, instead of segment S2 (or S1), traverses the membrane or that all six segments S1-S6 span the membrane cannot be excluded. In view of the ion selectivity of the sodium channel³⁵, however, it seems rather unlikely that segment S4, which has strong positive charge, is involved in the channel lining.

The voltage-dependent operation of the sodium channel implies that the structure responsible for gating is charged and is able to move in the membrane field, as postulated by Hodgkin and Huxley³ and subsequently confirmed by measurement of

the gating current⁴². The gating current is outward during activation, and available evidence suggests that both the activation and inactivation gates are located near the inner membrane surface⁴³. Noteworthy in this context is the presence of the unique, positively charged segment S4 in each of the four repeated homology units (see above) as well as the presence of a large excess of negatively charged amino acid residues over positively charged residues in the region between segment S6 of homologous repeat II and segment S1 of the repeat III. There are four segments each having 5-12 clustered acidic residues (segments composed of residues 802-806, 847-857, 894-910 and 942-955) in this region, which is assigned to the cytoplasmic side of the membrane (see Fig. 6B). These acidic segments are located at regular intervals of 31-40 residues, corresponding to the four hydrophilic segments observed in the hydropathy profile (see Fig. 6A). It is attractive to hypothesize that each of the four positively charged segments, possibly in conjunction with each of the four negatively charged segments, acts as voltage sensor, thus being involved in an activation gate. The presence of four homologous structures in a single sodium channel molecule would be consistent with the sigmoid activation kinetics characteristic of this channel³. Armstrong⁴⁴ postulates the presence of four to six closed states rather than three³ and claims that the successive transitions among them are fast and are each associated with a charge movement that amounts to only half that in the transition from the last closed state to the open state. Of interest in this context is the finding that the charge carried by the four individual acidic segments varies about twofold. Concerted movement of many negative groups and/or many positive groups as clusters even by a small distance could account for the gating current⁴⁴ and would induce a

Fig. 6 Hydropathy profile and predicted secondary structures (A) and proposed transmembrane topology (B) of the sodium channel protein. In A, the averaged hydropathic index of a nonadecapeptide composed of amino acid residues $i-9$ to $i+9$ has been plotted against i , where i represents amino acid number; the hydropathy indices of individual amino acids have been taken from ref. 29. The positions of the predicted structures of α -helix and/or β -sheet²⁸ that have a length of 10 or more residues are shown by open boxes. The positions of positively charged residues (lysine and arginine) and negatively charged residues (aspartic acid and glutamic acid) are indicated by upward and downward vertical lines, respectively. The locations of homologous repeats I, II, III and IV are shown by bars, and those of the non-homologous segments within the repeats by dashed lines. The positions of the characteristic segments S1-S6 in each repeat are indicated as follows: hatched boxes, segments S1 and S3 which generally contain negatively charged residues; stippled boxes, segment S2 with both positively charged and negatively charged residues; boxes with a plus sign, segment S4 with regularly spaced, positively charged residues; closed boxes, segments S5 and S6 without charged residues. In B, the four homology units spanning the membrane, which presumably surround the ionic channel, are displayed linearly. Segments S1-S6 in each unit are shown by cylinders marked as in A, and segments S1, S2, S5 and S6 are located within the membrane. Alternative possibilities of the transmembrane topology are discussed in the text. The regions containing clustered negatively charged residues are indicated by minus signs.

conformational change of the protein to open the channel. It is also intriguing to speculate that the region encompassing the negatively charged segments, after such a conformational change upon depolarization, might in turn be involved in the inactivation of the channel, under the assumption that the activation and inactivation mechanisms are coupled⁴⁴.

The region between segments S5 and S6 of homologous repeat I as well as IV is also rich in acidic residues, which are not as clustered as those in the negatively charged region discussed above. As the region between segments S5 and S6 is assigned to the extracellular side of the membrane, it is tempting to

hypothesize that the negatively charged residues in this region of homologous repeats I and IV, facing the outer end of the channel, are also involved in the ion selectivity of the channel and that these areas contain the binding sites for basic neurotoxins⁴.

We thank Dr Paul Berg and Dr Hiroto Okayama for providing us with their high-efficiency cloning system. This investigation was supported in part by research grants from the Ministry of Education, Science and Culture of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases.

The reactivity of anti-peptide antibodies is a function of the atomic mobility of sites in a protein

To study the nature of antigenic recognition, antibodies have been prepared against a set of peptide sequences representing both highly mobile and well-ordered regions of myohaemerythrin, based on X-ray crystallographic temperature factors. Anti-peptide antibodies against highly mobile regions react strongly with the native protein; anti-peptide antibodies from well-ordered regions do not. Mobility is a major factor in the recognition of the native protein by anti-peptide antibodies; this may be of general significance in protein-protein interactions.

ANTIBODIES against short chemically synthesized peptides are of great use in detecting proteins and studying their structure¹. The high frequency with which these antibodies react with intact folded proteins has raised several interesting theoretical issues; one of these is addressed by considering the differences between antibodies made against intact proteins and anti-peptide antibodies. The preparation of anti-protein antibodies involves the

injection of one of the most conformationally restricted states of the molecule, the folded protein; the resultant antibodies are tested for reactivity against proteins or peptides in a state of equal or less order. The binding of these antibodies is therefore sensitive to perturbations of protein structure such as fragmentation or denaturation². Conversely anti-peptide antibodies are made against a conformationally less restricted protein site and

then tested against a protein molecule which is almost always more ordered.

To explain why antibodies to short, flexible peptides frequently react with more ordered molecules, we have considered models involving local disorder in proteins^{3,4}. We envision that sites in proteins move through a range of conformations and bind to anti-peptide antibodies only when a conformation is displayed which the antibody recognizes. Thus the antibodies act as a 'sink', trapping particular local conformations in mobile areas of proteins. Here we test this model's prediction that mobile sites in proteins will be recognized preferentially by anti-peptide antibodies.

Differential mobility

Refined high resolution X-ray crystal structures of molecules identify atomic positions and provide empirically determined information about atomic mobility in the form of the atomic temperature factors defined by $8\pi^2 u^2$, where the mean square displacement u^2 is averaged over time and the crystal lattice⁵. Patterns of temperature factors can reveal the lower-frequency concerted motions of groups of atoms, indicating the relative conformational variability of different regions^{6,7}; high factors indicate shallow potential wells (low energy barriers between

different conformations) allowing access to multiple conformations at biological temperatures. Individual atomic temperature factors are named for the temperature dependence of the velocity of atomic motion and the corresponding thermal energy available for surmounting these conformational potential energy barriers, rather than for local temperature differences within the molecule. (For simplicity, we use the suggestive terms 'hot' and 'cold' to refer to highly mobile (high temperature factors) and well-ordered regions (low factors), respectively.) Temperature factors may also reflect static disorder in the crystal, error in the absorption corrections, improper scaling and errors in the interpretation of the electron density. By examining the overall pattern of atomic temperature factors for a highly refined protein structure which has been solved independently in different crystal systems, the differential mobility of various regions of the molecule can be isolated from these other factors⁸.

To characterize patterns of temperature factors on protein surfaces, we examined 22 X-ray structures available from the Brookhaven Protein Data Bank⁹. We mapped temperature factors onto the solvent-accessible molecular surfaces¹⁰ and found them to be characterized by areas of both high and low mobility. Regions of low mobility were often, but not always, associated with interfaces between subunits in multimeric proteins or between adjacent molecules in the crystal lattice; such contacts were characterized by a lower than average ratio of side-chain to main-chain temperature factors. Otherwise, the average main-chain and atomic temperature factors also reflected the expected relative mobility of different parts of the molecular surface based on the constraints from underlying stereochemical interactions.

The differential mobilities of protein surfaces suggested to us that crystallographic temperature factors might be relevant in antibody-antigen recognition, and that this could be examined experimentally with anti-peptide antibodies. To select a protein for this study, we compiled a database of crystal structures known at sufficient resolution to provide accurate parameters of thermal mobility. We then eliminated proteins with considerable sequence homology to rabbit proteins (thus avoiding immunological tolerance) and proteases (which could complicate the immunoassays). We chose myohaemerythrin from the remaining protein structures for its well-refined temperature factors, wide range of mobility at the molecular surface and contiguous regions of the amino acid sequence characterized by either high or low mobility.

Myohaemerythrin belongs to the haemerythrin family of oxygen-carrying proteins found in some invertebrates. The structural fold for this family of proteins is an antiparallel bundle of four helices¹¹ (A, B, C and D) surrounding a two-iron centre at the active site, with a loop region at the N-terminus and shorter loops between the helices and at the C-terminus. Three-dimensional crystal structures with temperature factors have been refined at high resolution for monomeric myohaemerythrin from the marine worm *Themiste zostericola* (S. Sheriff, W.A.H. and J. L. Smith, unpublished results) and octameric haemerythrin from *Themiste dyscrita*¹². The structure of myohaemerythrin is known to 1.7 Å resolution in two crystalline directions (*a* and *c*) and to 1.3 Å in the third direction (*b*), with a crystallographic residual error of 0.159 and a r.m.s. deviation from ideal bond lengths of 0.017 Å. The related structure of haemerythrin is known to a resolution of 2.0 Å, with a residual error of 0.175 and a r.m.s. deviation from ideal bond lengths of 0.026 Å. The temperature factors for these two crystal structures are unique in being empirically corrected for packing contacts⁴⁵. Myohaemerythrin (Fig. 1a) demonstrates variable surface mobility of different intra-domain structural elements typical of high resolution protein structures. Before adjustment for the effects of crystal contacts, the A and D helices are relatively highly ordered, the C helix is highly mobile and the B helix varies from being relatively well ordered at the N-terminal end to relatively mobile at the C-terminal end. The 'glowing coal' temperature scale (Fig. 1a) delineates clearly this partitioning of the exposed surface of myohaemerythrin into regions of high and low mobility.

← **Fig. 1** Stereo pairs showing the α -carbon backbone and the molecular surface of myohaemerythrin colour-coded by temperature factor. The molecular surface calculation^{25,32} rolls mathematically a water-sized probe sphere (1.4 Å radius) representing a solvent water molecule over the van der Waals' surface of the protein. All molecular surface calculations used individual van der Waals' radii that included implicit hydrogen atoms^{33,34}. Using the general purpose graphics modelling language GRAMPS³⁵ and the molecular modelling program GRANNY³⁶, the protein skeletal model together with its associated molecular surface (shown as a transparent set of colour-coded dots) was displayed interactively using vector computer graphics. In these figures, the terms front and back refer to the stereo directions towards and away from the reader, respectively, while all other directional terms refer to locations within the plane of the page. **a**, Patterns of mobility on the molecular surface of myohaemerythrin. This stereo view shows the solid external molecular surface colour-coded by the average main-chain temperature factors using a radiating-body colour scale. The molecule is oriented with the helices vertical, and the two-iron centre towards the top (*b* shows the skeletal model in the same orientation). The darkest colours (lowest temperature factors) are associated with the A helix (lower right) and the brightest colours (highest temperature factors) with the C helix (upper left). In these temperature factors, before adjustment for the effect of crystal contacts, the B helix (centre) varies from low (bottom, centre) to high (top, centre) temperature factors. The low temperature factors in the B helix apparently result from crystal packing contacts. This raster colour graphics representation was calculated using RAMS³⁷ and displayed on an AED raster graphics display. **b**, The synthetic peptide positions shown on the myohaemerythrin α -carbon backbone. Peptides are coloured to identify hot (red), cold (blue) and hot/contact (yellow) types of mobility, (magenta, not studied). The iron ions are shown by magenta spheres and bonds. The side chains of the iron liganding residues (His 25, His 54, Glu 58, His 73, His 77, His 106 and Asp 111) are colour-coded to match the peptide sequences in which they occur. Residues at the end of each non-nested peptide are labelled at their respective α -carbons. Hot peptides 57-66, 63-72, 69-82, 73-82 appear upper left, cold peptides 22-35, 26-35 right, 96-109, 100-109 at the centre (back), hot/contact peptides 3-16, 7-16 at the right (back) and 37-46, 42-51 at the centre (front). **c**, The location and exposed molecular surface of peptide sequences shown in the same orientation as **a** and **b**. The molecular surface and α -carbon backbone of the peptides are colour-coded to identify four categories of peptides: highly mobile in the crystallographic temperature factors (red backbone, molecular surface), highly mobile in the temperature factors adjusted for crystal contacts (yellow backbone, red molecular surface), relatively well ordered (blue backbone, molecular surface) and peptides not studied (magenta backbone, molecular surface). The peptides studied all show large amounts of exposed surface area. **d**, The location and exposed molecular surface of peptide sequences as described for **c**, but shown in the opposite orientation.

Fig. 2 Plot adapted from Sheriff *et al.*⁴⁵ of the average main-chain temperature factors along the polypeptide chain before (dashed line) and after (solid line) adjustment for crystal contacts. Regions 1–17 (N-terminal loop), 38–50 (N-terminus of the B helix), and 85–94 (C–D loop) show the greatest increase in relative mobility when corrected for crystal contacts. The 118 residue amino acid sequence of myohaemerythrin³⁸, corrected by a sequence inversion of residues 34 and 35 revealed by X-ray crystallographic studies (J. L. Smith and W.A.H., unpublished results), is shown in one-letter code (A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine). 10 and 14 residue sequences of the protein chosen for peptide synthesis are indicated by sequence-numbered bars. To allow coupling to the immunological carrier protein, an additional cysteine residue not found in the primary sequence was synthesized at the C-terminus of each peptide. Additionally, cysteine 35 in peptides 22–35 and 26–35 was replaced with a serine to avoid multiple coupling to the carrier, while maintaining peptides of a fixed length.

Methods: Peptides were synthesized as described previously³⁹ by the solid phase method^{40,41} using a Beckman model 990B peptide synthesizer. The initial amino acid resin was prepared by esterification of Boc-(MeoBzl)-Cys-OH (2.0 g anhydrous-caesium salt, 4.3 mequiv.) to chloromethylated resin (polystyrene/1% divinylbenzene, bio-beads S.X.-1, 200–400 mesh, 0.70 mmol g⁻¹) in 25 ml anhydrous dimethylformamide (DMF) by stirring for 24 h at 50 °C. A threefold excess of caesium salt over active chloride polymer gives almost complete substitution. Substitution was determined to be 0.55 mequiv. g⁻¹ by the picric acid test and amino acid analysis, and 0.53 mequiv. g⁻¹ following HCl-propionic acid hydrolysis. For each synthesis, 1.0 g (0.53 mequiv.) of Boc-(MeoBzl)-Cys resin was used. The following side-chain protecting groups were used: *O*-Br-Z for lysine and tyrosine; *O*-benzyl for threonine, serine, aspartic acid and glutamic acid; tosyl for arginine; *N*-formyl for tryptophan; *N*-dinitrophenyl for histidine. Protected amino acids (Vega Biochemicals or Peninsula Laboratories) were recrystallized from the appropriate solvent to give single spots on TLC (chloroform/acetic acid = 15:1 or chloroform/methanol = 10:1). All couplings were carried out using a 10-fold excess of Boc-AA-OH. For asparagine and glutamine, an equimolar amount of *N*-hydroxybenzotriazole was added to the protected amino acid and DMF was used as the solvent. All coupling reactions were ≥99% complete by the picric acid test. The removal of dinitrophenyl from histidine-containing peptides was accomplished with *N*-methyl mercaptoacetamide⁴² in DMF by mixing with the resin-bound peptide for 15 min. Removal was >95%. The resin bound protected peptides (500 mg to 2.5 g, 0.12–0.60 mequiv.) were treated with twice their weight of anisole and with 40 times their volume (relative to weight) of anhydrous HF at 4 °C for 1 h. For peptides containing glutamic acid, 5% v/v pyridine was added to the HF to prevent anisylation. After evaporating the HF with a stream of N₂, the red/yellow residue was mixed with anhydrous ether (50 × w/v) and stirred vigorously for 15 min; after repeating the ether extraction three times, the white residue was filtered and dried *in vacuo*. This dried resin-peptide mixture was extracted with 5% HOAc, lyophilized and amino acid analysis performed (~90% removal of the peptide from the resin). For peptides containing tryptophan, the *N*-formyl protecting group was removed from the peptide by treatment for 1.5 min at pH 11.5 (NaOH) in the presence of hydrazine. The amino acid analysis was within 5% of the theoretical value for all peptides. All peptides were coupled²⁷ to the immunogenic carrier protein KLH through the C-terminal cysteine of the peptide using *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) as the coupling reagent⁴³. Two rabbits were immunized with each peptide in a course of 3 injections of 200 µg peptide-coupled KLH (in complete Freund's adjuvant (1:1) subcutaneously on day 0, in incomplete Freund's adjuvant (1:1) subcutaneously on day 14, and with 4 mg of alum intraperitoneally on day 21).²⁷ Rabbits were bled 10 days after the third injection and boosted 3 months from the last injection and bled again 7 and 14 days later.

Myohaemerythrin peptides

Peptides, representing both helical and non-helical regions of myohaemerythrin, were selected on the basis of main-chain temperature factors averaged by residue, because the main-chain mobility reflects the global conformational variability of the protein (Fig. 1b). Three of the hot peptides include residues liganding the irons; in the native protein the mobility of these sequences is limited to conformations that do not disrupt the metal-ligand geometry.

Figure 1b–d shows the locations and exposed surfaces of the synthesized peptides in the protein. Of the exposed molecular surface area of myohaemerythrin (5,846 Å²), our synthesized peptides account for 4,005 Å² or ~69%. The four peptides synthesized for each of three categories encompass roughly

equal parts of the protein surface area: 23.0% hot, 19.3% cold and 26.2% hot/contact (hot after correction for crystal contacts), and all peptides have large areas of exposed molecular surface available for interaction with antibodies (Fig. 1c, d). Highly exposed amino acid residues tend to be less hydrophobic and, due to their external, relatively unconstrained position, more highly mobile than internal residues^{13,14}. We chose peptides to minimize differences in average exposed area and hydrophobicity per residue. Although there is some correlation of exposed area and mobility among the selected peptides, this is much stronger for side-chain than for main-chain atoms (Table 1). In fact, peptides with very similar average exposed areas may either be cold (peptides 22–35, 26–35 and 96–109) or hot (7–16, 42–51 and 57–66). There is very little correlation between temperature factor and average hydrophobicity per residue for the peptides chosen (Table 1).

Fig. 3 Comparison of the anti-protein reactivities of antibodies raised against hot, cold, and hot/contact peptides. Lanes are representative polyacrylamide gel electrophoresis of the immunoprecipitates in the presence (+) and absence (-) of competing peptide. Lane *a*, control normal rabbit serum; lane *b*, hot peptide 57-66; lane *c*, cold peptide 26-35; lane *d*, hot/contact peptide 3-16; lane *e*, intact myohaemerythrin. Radiolabelled pellets from the immunoprecipitation were dissolved in 50 μ l of sample buffer⁴⁴ containing 2% SDS, 5% 2-mercaptoethanol and 0.001% bromophenol blue, boiled for 3 min, centrifuged to remove *S. aureus*, subjected to electrophoresis on 12.5% SDS gels, and autoradiographed. Faint bands representing aggregated states of myohaemerythrin can also be seen.

The sequence location and identity of the synthesized peptides is overlaid on the plot of the average main-chain temperature factors in Fig. 2. The 12 peptides synthesized include 83 of the total 118 residues or ~70% of the myohaemerythrin sequence. The clear division of the peptides into highly mobile and well-ordered categories is apparent in the adjusted temperature factors: two of the helices are relatively highly ordered, whereas the remainder of the structure shows significantly more mobility.

Antibody-reactive regions

To elucidate the role of molecular surface mobility in the recognition of the native protein, we raised polyclonal antibodies against synthetic peptides with each selected sequence (Table 2). Polyclonal antibodies enabled us to sample the entire range of allowed conformations for the injected synthetic peptide, whereas monoclonal antibodies would select single, possibly atypical conformations of each peptide.

The anti-peptide antisera were originally assayed for reactivity against the homologous immunizing peptide by enzyme-linked immunoabsorbent assay (ELISA). All but one of the synthetic peptides are immunogenic (Table 2); their relative immunogenicity is not correlated with their mobility. We next assayed the anti-peptide antisera for reactivity with myohaemerythrin (Table 2). All antisera raised against cold peptides (22-35, 26-35, 96-109 and 100-109) gave negative or low reactivity with the protein, whereas all antisera raised against hot peptides (excluding peptide 42-51, which did not raise any antibodies) gave higher reactivity against the protein. Of the antisera against hot peptides, those with the lowest myohaemerythrin reactivity (57-66 and 63-72) also had the lowest reactivity against their respective homologous immunizing peptides.

We used the method of Farr¹⁵ to estimate the avidity or effect of dilution on the binding of anti-peptide antisera to myohaemerythrin at five concentrations (1, 5, 10, 50 and 100 pmoles). The relative averaged avidity of the anti-peptide antisera against the protein (peptides 3-16 > 7-16 > 37-46 > 57-66 > 63-72, 69-82, 73-82, 96-109) matched the pattern of relative reactivity, antisera with higher titres generally showing greater avidity. (The negative or low reactivity of the remaining anti-peptide antisera with the protein precluded measurement of their avidities.) ELISA analyses may involve some denaturation of the target protein. We therefore assayed immunoprecipitation in conditions preserving the native structure of myohaemerythrin. Retention of the characteristic visible spectrum with a 338 nm peak¹⁶ (due to the iron centre) verified that the ligand environment remains unchanged. The results of these immunoprecipitation studies and the associated gel electrophoresis analysis (Table 2, Fig. 3) are consistent with the ELISA analyses.

To confirm the specificity of the anti-peptide antisera, we also performed immunoprecipitation studies in the presence of homologous and heterologous peptides (Table 2, Fig. 3). The anti-myohaemerythrin reactivity of antisera raised against the hot peptides was strongly inhibited by incubation with the corresponding homologous peptide, whereas incubation with the irrelevant heterologous peptide (synthesized from a sequence for influenza virus haemagglutinin) did not inhibit anti-myohaemerythrin reactivity, thus confirming the specificity of the antisera. Interestingly, antisera against cold peptides that showed low reactivity with the protein (22-35, 96-109) were, at most, only slightly inhibited by incubation with the corresponding homologous peptides. This suggests that the anti-myohaemerythrin reactivity of antibodies raised against these

Table 1 Myohaemerythrin peptide data

Sequence position	Secondary structure	Type	Mobility			Average exposed area	Average hydrophobicity
			Main*	Main	Side*

Peptides are numbered by their respective sequence position in myohaemerythrin. All mobilities are derived from the temperature factor data for the intact protein⁴⁵. Peptides are classified into three types of mobility: hot (high average main-chain temperature factors), cold (low average main-chain temperature factors*) and hot* (hot/contact, high average main-chain temperature factors after correction for the effects of crystal contacts). Mobility in $\text{\AA}^2$ is expressed as average main chain* (calculated from the atomic temperature factors for N, C α , C, O atoms adjusted for crystal contacts), average main chain (calculated from the atomic temperature factors for N, C α , C, O atoms), and average side chain* (calculated from the atomic temperature factors for side-chain atoms adjusted for crystal contacts). Average exposed area in $\text{\AA}^2$ is calculated using the molecular surface program MS²⁵. Average hydrophobicity is calculated using the Eisenberg consensus scale²⁶. Properties were first averaged for each residue, then these residue averages were averaged for each peptide.

Fig. 4 Stereo views showing the correlation between the mobility of sites in a protein and their reactivity with anti-peptide antibodies. The α -carbon backbone is colour-coded by antigenic reactivity based on the immunoprecipitation results (Table 2): red, high ($> 3,500 \text{ c.p.m.}$), yellow, medium ($2,000-3,000 \text{ c.p.m.}$), blue, low ($< 200 \text{ c.p.m.}$), magenta, not studied. The exposed molecular surface is colour-coded by average adjusted main-chain temperature factors (Table 1): red, hot ($\geq 27 \text{ \AA}^2$), yellow, medium ($22-27 \text{ \AA}^2$), blue, cold ($< 22 \text{ \AA}^2$). To identify the portions of the molecular surface associated with each synthesized peptide sequence, the myohaemerythrin molecule is dissected into individual peptides (backbone and associated molecular surface) shown in a slightly exploded view. Since the peptides were coupled onto the KLH carrier at the C-terminal amino acid, overlapping and nested peptide sequences were assigned the level of reactivity associated with the sequence of the N-terminal portion of the relevant peptide. *a*, The following peptide regions (correspondence of secondary structure descriptions to sequence positions defined in Table 1) show the correlation of their temperature factors with antigenic reactivity: the N-terminus (red backbone and surface, lower right), the A helix (blue backbone and surface, centre), the A loop (red backbone and surface, lower left, front) and the C-terminal end of the B helix (red and yellow backbone and surface, upper left). *b*, The relationship is apparent for the remaining peptide regions: the non-overlapping fragment of the B-C loop (yellow backbone and red surface, top), the C helix (red and yellow backbone and surface, upper right), and the D helix (blue and yellow backbone and surface, lower left).

cold peptides may largely represent either nonspecific binding or low avidity.

The striking correlation seen in both types of immunoassay between the mobility of sites in a protein and their reactivity with anti-peptide antibodies is seen when the reactivities of the anti-peptide antibodies are mapped onto the α -carbon backbone and the average adjusted main-chain temperature factors mapped onto the external molecular surface (Fig. 4). Of the cold peptides, only antibodies to peptide 96-109 have reactivity with intact myohaemerythrin; this peptide has four residues with higher temperature factors on its N-terminal end. Of the hot peptides, the N-terminal loop peptide 3-16 represents the target site with the highest mobility and reactivity with anti-peptide antibodies. Reduced mobility due to structural constraints in myohaemerythrin resulting from the metal liganding may modulate the degree of antigenic reactivity. In the immunoprecipitation assays, antisera against the shorter of

the two nested peptides containing two metal ligands in the intact molecule (73-82) have the lowest anti-protein reactivity of any hot peptide antisera. These results support the correlation between mobility and reactivity with anti-peptide antibodies.

Part of the effect seen in these experiments could be the result of differences in the level of antibody raised against the individual peptides. Our basic findings remained the same when reactivities were normalized as a function of the anti-peptide titres: thus expressed, the anti-protein reactivities improved for antisera against hot peptides and changed little for those against cold peptides. Furthermore, we found that the increase in anti-peptide titres after the rabbits received booster injections of peptides led to increases in anti-myohaemerythrin reactivity for the antibodies raised against the hot peptides, compared with little or no increase in reactivity for the antibodies raised against the cold peptides (data not shown).

Conclusions

The ability of anti-peptide antibodies to recognize their corresponding intact folded proteins is best understood as a dynamic process which is most favoured when the conformation of the peptide immunogen approximates the target site in the protein and that site is mobile. The relative contributions of each factor to the success of an immunogen are difficult to assess and may vary from peptide to peptide. Our data suggest that recognition involves the interaction of antibodies with sites in the protein which can adopt multiple conformations that may differ from the average structure seen by X-ray crystallography. One may envision a process in which the initial interaction with the antibody is sufficient for recognition of the appropriate site, after which considerable induction of shape may take place.

Reactivities of the various anti-peptide antisera raised in pairs of rabbits were assayed against the antigen in the solid phase using ELISAs and against the antigen in solution using immunoprecipitation. ELISA titres are expressed as the reciprocal of antibody dilution extrapolated to bind 50% of 50 pmol antigen per well. ELISA: Assays followed the procedure described by Green *et al.*²⁷ 50 pmoles antigen (synthetic peptide or myohaemerythrin molecule) in phosphate-buffered saline (PBS, 10 mM sodium phosphate, 0.15 M NaCl, pH 7.2) were added to each well of a polystyrene microtitre plate and dried overnight at 37 °C. The dried antigen was then fixed to the plate by treatment with 50 μ l of methanol per well for 5 min at room temperature. The plates were coated for 4 h with a solution of non-fat dry milk (BLOTTO, ref. 28) to block nonspecific absorption of antibodies to the plate. Following the addition of 25 μ l antiserum (serially diluted with the same solution) to each well, the plates were incubated overnight at room temperature and the unbound antibody was washed off with water. The antigen-antibody complex was reacted with goat anti-rabbit IgG coupled to glucose oxidase²⁹. After removal of excess goat anti-rabbit IgG with water, this sandwich complex was measured enzymatically by the addition of enzyme substrate. For less denaturing (wet plate) ELISAs, the antigen was attached to the plates by overnight incubation in 15 mM saline in 10 mM phosphate buffer, pH 9.0. Non-immunogenic peptide 42-51 continued to give negative results in repeated ELISA experiments. Rabbit antisera against the intact myohaemerythrin protein were tested by ELISA for reactivity with the protein and with the synthetic peptides. The anti-protein antisera showed high reactivity (titres > 1,280) against myohaemerythrin, but did not react with any of the tested synthetic peptides. Controls showed no cross-reactivity between kehole limpet haemocyanin (KLH) and myohaemerythrin and no anti-myohaemerythrin reactivity in preimmune serum. Immunoprecipitation: Myohaemerythrin was radiolabelled with ^{125} I by the chloramine-T reaction³⁰ to a final incorporation of about 25 μ Ci μ g⁻¹. After dialysis, 10⁶ c.p.m. of ^{125} I-myohaemerythrin in PBS were reacted with 10 μ l of anti-peptide antiserum for 60 min on ice. The antigen-antibody complexes were precipitated with formalin-fixed *Staphylococcus aureus*. The pellets were washed once with RIPA buffer (PBS containing 1% Nonidet P-40, 0.05% sodium deoxycholate and 0.1% SDS) and twice with 500 mM LiCl, 100 mM Tris (pH 8.5), then analysed for radioactivity. In peptide competition experiments, the anti-peptide antibodies were preincubated for 60 min with 100 μ g peptide in PBS before the addition of ^{125} I-myohaemerythrin. Western blot analysis: The correlation of mobility with antigenic reactivity was also studied by Western blot analysis³¹. Following polyacrylamide gel electrophoresis of myohaemerythrin in denaturing conditions (the samples were boiled in the presence of 2% SDS and 5% 2-mercaptoethanol), the protein was transferred to a nitrocellulose filter and incubated with selected anti-peptide antisera. Detection of the bound antisera with ^{125} I-labelled *S. aureus* protein A showed that the antisera against cold peptides did not react well with myohaemerythrin in these conditions, whereas antisera against hot peptides showed relatively strong reactivity.

* Average of two independent experiments, after correction for nonspecific binding.

† 100.0 % minus per cent of activity remaining in the presence of the peptide.

Mobility is thus involved in both adoption of protein conformations suitable for recognition by the antibody and the degree to which a given region can be induced into a conformation that fits the antibody binding site.

For proteins in solution, the range and extent of mobility are probably greater than those calculated from the average main-chain temperature factors; dynamics calculations indicate that conformational flexibility is greater than that seen in the X-ray crystal structures¹⁷. In myohaemerythrin, the highest temperature factors predict average isotropic displacements between ± 0.7 and ± 0.9 Å for the main and side chains, respectively. Rather than defining exactly the excursions of individual residues¹⁸⁻²⁰, however, these high values identify areas with relatively low energy barriers between alternate conformations. The overall mobility does not imply any complete local unfolding in myohaemerythrin, as no visible spectroscopic change in the ligand environment of the two iron atoms occurs in the solvent and salt conditions used in the present study. The fact that strong protein-reactive antibodies can be induced by peptides representing highly mobile sites in the protein that contain iron binding residues (Fig. 1b) indicates that mobility, but not complete local disorder, is important for antigenic reactivity.

The anti-protein reactivity of antibodies to synthesized myohaemerythrin peptides correlates better with the mobility of the target sites than with their exposed surface area. The cold peptides 22-35, 26-35 and 96-109 have similar average exposed surface areas to hot peptides 7-16 and 57-66, but much less reactive antisera. Thus, the apparent relationship between exposed area and antigenic reactivity²¹ may actually reflect the increased mobilities of turns, loops and other highly exposed areas. As a large percentage of the exposed molecular surface (80% in myohaemerythrin) belongs to highly mobile residues, our results are consistent with studies¹ showing that most anti-peptide antibodies react with the corresponding intact protein.

Protein-protein interaction is a complex process involving many characteristics of the molecular surface, including shape complementarity and hydrophobicity of the interacting molecular surfaces²². The mapping of electrostatic potential onto molecular surfaces^{23,24} has revealed the importance of electrostatic forces in intermolecular interactions. Our present results showing a correlation between the mobility of sites in a protein and their reactivity with anti-peptide antibodies suggest that molecular mobility is an essential part of the antigenic recognition process and perhaps of protein-protein recognition in general. The distinguishing feature of anti-peptide antibodies is their predetermined specificity. Elucidation of the amino acid sequence of a protein should allow the use of site-specific anti-peptide antibodies for the investigation of the role of conformational flexibility in protein-protein recognition processes.

The sample of myohaemerythrin was prepared by the late G. L. Klippenstein, University of New Hampshire. We thank S. Sheriff for advice and assistance in the analysis of the protein coordinates and temperature factors; Leonid Volfson, Susan Gruber, Sarah Hoffmann, Susie Morrell and Andrea Struthers for technical assistance; Michael Connelly, Ian Wilson, Michael Pique and Wilfred van Gunsteren for useful discussions. J.A.T. and E.D.G. are Damon Runyon-Walter Winchell Fellows. This work was supported in part by a NIH program-project grant.

Note added in proof: Recent studies show that existing antibodies bind regions of high mobility in tobacco mosaic virus coat protein, lysozyme and myoglobin⁴⁶ and in other known protein structures⁴⁷.

Near-infrared observation of the circumsolar dust emission during the 1983 solar eclipse

K. Mizutani, T. Maihara, N. Hiromoto* & H. Takami

Department of Physics, Kyoto University, Kyoto 606, Japan

A near-infrared excess emission superposed on the coronal continuum at $\sim 4R_{\odot}$ from the Sun was first observed at $2.2\text{ }\mu\text{m}$ by Peterson¹ and MacQueen² during the total solar eclipse in 1966, and was later confirmed by MacQueen² using a balloon-borne coronagraph. Two subsequent observations were made; one³ obtained a similar result, while the other⁴ detected no excess emission. The excess emission was thought to be due to thermal radiation by a dust cloud around the Sun, and interpreted to be interplanetary dust². Brecher *et al.*⁵, on the other hand, have proposed that the ring is composed of much larger objects (of about 10 km diameter). To obtain more definite information, we have therefore carried out observations of near-infrared brightness distributions of the solar corona, using a balloon-borne photometer at a balloon altitude, during the total eclipse on 11 June 1983 in Indonesia. As we report here, emissions in excess of the strong coronal background emission were recorded in some of the scans at $\sim 4R_{\odot}$ from the Sun. The spatial distribution of the excess emission implies the existence of a circumsolar ring of dust lying approximately in the ecliptic plane.

The balloon-borne instrument we used for near-infrared photometric scanning consisted of a 16-cm Cassegrain telescope and a simultaneous four-band photometer in a reaction wheel-stabilized gondola, together with a high-sensitivity television camera. The photometer had four 4-element PbS detector arrays thermoelectrically cooled at separated foci with three beam-splitters. The infrared bands investigated were $1.25\text{ }\mu\text{m}$ ($\Delta\lambda = 0.24\text{ }\mu\text{m}$), $1.65\text{ }\mu\text{m}$ ($\Delta\lambda = 0.23\text{ }\mu\text{m}$), $2.25\text{ }\mu\text{m}$ ($\Delta\lambda = 0.28\text{ }\mu\text{m}$) and $2.8\text{ }\mu\text{m}$ ($\Delta\lambda = 0.7\text{ }\mu\text{m}$). The field of view of each element was $0.3R_{\odot} \times 0.3R_{\odot}$, and the arrays were orientated perpendicular to the scan path.

A 15,000-m³ balloon was successfully launched by a joint team of ISAS (the Institute of Space and Astronautical Science, Japan) and LAPAN (Indonesian National Institute of Aeronautics and Space) at the Watukosek Balloon Base in East Java. Virtual tracking of the eclipsed Sun at a floating altitude of 30 km was performed by rotating the magnetometer stage at an appropriate rate after the desired instrument orientation had been obtained. The attitude stability was better than 10 arc s ($\sim 0.01R_{\odot}$). Absolute positional error was $<0.2R_{\odot}$ in the scan

direction and $<0.3R_{\odot}$ in the perpendicular.

Scanning was performed by small-amplitude oscillation around the cross-elevation axis. The width of the scan was 5° ($20R_{\odot}$) and its rate was 0.05 deg s^{-1} ; this allowed $1\frac{1}{2}$ complete scans between $6R_{\odot}$ on the west side of the Sun and $14R_{\odot}$ on the east side. Scan paths crossed the ecliptic plane on the west side at $\sim 4R_{\odot}$ with an inclination of $\sim 7^{\circ}$. The configuration of the scan path and beam positions of each detector are shown in Fig. 1. In-flight and post-flight calibrations have indicated possible errors of $\pm 30\%$ in absolute brightness determination. Polarization at $2.25\text{ }\mu\text{m}$ was also measured using a rotating half-wave plate and a fixed polarizer. The result of the polarization measurement will be described elsewhere.

Figure 2 shows brightness distributions in each band on the west side of the Sun along the scan path. At $1.65\text{ }\mu\text{m}$, a definite excess over the smooth coronal component is seen between $2.8R_{\odot}$ and $4.5R_{\odot}$ from the Sun on the west side, showing a peak at $3.8R_{\odot}$. The brightness of the excess component at $3.8R_{\odot}$ on the west side is $6 \times 10^{-7}\text{ W cm}^{-2}\text{ }\mu\text{m}^{-1}\text{ sr}^{-1}$. A weaker excess is also seen between about $3R_{\odot}$ and $4.4R_{\odot}$ on the east side, where the peak again occurs at $3.8R_{\odot}$. The brightness of the excess component at $3.8R_{\odot}$ on the east side is $2.2 \times 10^{-7}\text{ W cm}^{-2}\text{ }\mu\text{m}^{-1}\text{ sr}^{-1}$. A relatively small but obvious excess emission is also seen in the $1.25\text{-}\mu\text{m}$ profiles from about $3.2R_{\odot}$ to $4.5R_{\odot}$ on the west side of the Sun, where scans have just crossed the ecliptic plane (see Fig. 1). The peak is again at $\sim 3.8R_{\odot}$ and the brightness of the excess component is $3.7 \times 10^{-7}\text{ W cm}^{-2}\text{ }\mu\text{m}^{-1}\text{ sr}^{-1}$. The contribution of stray light from the strong inner corona has been estimated from independent laboratory data for the off-axis rejection rate. The effect is not serious in the region further than $1.8R_{\odot}$ in $1.65\text{-}\mu\text{m}$ and $2.25\text{-}\mu\text{m}$ bands, or further than $3.0R_{\odot}$ in $1.25\text{-}\mu\text{m}$ and $2.8\text{-}\mu\text{m}$ bands. Any error due to such stray light is safely below 30% of the above excess emissions.

In the $2.25\text{-}\mu\text{m}$ band, we have failed to detect definite peaks larger than the 3σ detection limit of $1.2 \times 10^{-7}\text{ W cm}^{-2}\text{ }\mu\text{m}^{-1}\text{ sr}^{-1}$, owing to degraded sensitivity in this band. However, a small feature could be discerned at about $4R_{\odot}$ on the west side, where the brightness is $1 \pm 0.4(1\sigma) \times 10^{-7}\text{ W cm}^{-2}\text{ }\mu\text{m}^{-1}\text{ sr}^{-1}$, roughly consistent with the previous observations of Peterson¹ and MacQueen². We found no definite excess component in the $2.8\text{-}\mu\text{m}$ band at the 3σ level of $1.2 \times 10^{-7}\text{ W cm}^{-2}\text{ }\mu\text{m}^{-1}\text{ sr}^{-1}$.

Figure 3 shows a near-infrared energy distribution of the excess component obtained from the present observation, together with previous $2.2\text{-}\mu\text{m}$ data. It has a maximum at $1.65\text{ }\mu\text{m}$ and drops off at both shorter and longer wavelengths, especially between 1.65 and $2.25\text{ }\mu\text{m}$, differing significantly from the solar spectrum. Therefore, we argue that the excess emission component is not caused by scattered light but is due mainly to thermal radiation of circumsolar dust particles of appropriate composition to produce the spectrum.

* Present address: Radio Research Laboratories, Koganei 184, Japan.

Fig. 1 The scan path of the telescope beam and the projected focal plane array of detectors. J, H, K and L' denote the 1.25-, 1.65-, 2.25- and 2.8- μm bands, respectively. Data from two detectors of the 1.65- μm band, indicated by hatched squares, were not used for data analysis, due to anomalous large noise.

Lamy has proposed⁶ that the near-infrared excess emission may be caused by silicate grains such as obsidian particles lying just outside a dust-free zone, while Mukai *et al.*⁷ have suggested a two-component model of obsidian and graphite. However, the spectral features observed by us are not consistent with these materials, even taking into account the large uncertainty in the data at longer wavelengths. One interpretation we have envisaged is that the emission in question is accounted for by thermal emission from olivine particles of the order of 100 μm in radius at a temperature of $\sim 1,300$ K. Olivine possesses a strong absorption band between 0.8 and 1.7 μm , and hence is more emissive within this band. Smaller olivine particles seem unlikely because the intensity of scattered light would obliterate the thermal radiation, making the spectrum appear solar. As an illustration, the thermal emission spectrum of olivine of radius 100 μm at a temperature of 1,300 K is shown in Fig. 3.

Our suggestion that the circumsolar dust may consist of relatively large particles composed mainly of olivine is based on recent studies of interplanetary dust and its mineralogy. Weiss-Wrana⁸ has shown that the principal properties of the zodiacal light ('the false dawn') are well represented by opaque irregularly-shaped chondritic particles in the size range 20–120 μm . Most stratospheric micro-meteorites, known as Brownlee particles⁹, have an opaque, black appearance and a composition similar to CI carbonaceous chondrites. Furthermore, olivine

is known to be a major constituent of extraterrestrial solids such as stony meteorites. Finally, Hashimoto *et al.*¹⁰ have demonstrated, in experiments on the thermal metamorphism of C2 type carbonaceous chondrites, that the matrix (mineralogically amorphous) becomes olivine when heated in a low pressure environment to $>1,000$ K.

The infrared spectrum we have observed can thus be interpreted as being due to the thermal metamorphism of dust particles as they spiral down to the hot region of the circumsolar dust cloud. However, the orbital radius at which the emission peaks were recorded must be explained in terms of a time-dependent vaporization process of relatively large particles (of the order of 100 μm) having optical properties that are susceptible to temperature changes—ranging from opaque in distant regions to a more transparent (olivine-like) nature in nearer and thus hotter regions around the Sun. A problem concerning the equilibrium temperature of such particles as envisaged here is that, according to Röser and Staude¹¹, a 100- μm olivine particle would have a temperature of 2,000 K at $\sim 4R_{\odot}$.

The present observations also provide information about the spatial distribution of dust, although the scan paths were such that a genuine central peak on the east side of the ecliptic plane was missed. As shown in Fig. 2, the excess component of the 1.65- μm band seems to extend from $2.8R_{\odot}$ to $4.5R_{\odot}$, with a small peak at around $3.8R_{\odot}$. (These features bear some

Fig. 2 Brightness distributions of each band observed on the west side of the Sun. The data are averaged over every $0.15R_{\odot}$ except for the 2.8- μm band inside $4.4R_{\odot}$, where the interval is $0.08R_{\odot}$.

Fig. 3 Energy spectrum of the excess emission component. Previous observations at 2.2 μm are also shown: $\blacktriangle$, ref. 1; $\blacksquare$, ref. 2. The solid curve represents the thermal radiation of an olivine particle of radius 100 μm at a temperature of 1,300 K. The dashed line is a 1,300 K black body curve for comparison.

resemblance to the 2.2- μm profile found by Peterson¹², but differ in that our data show no steep trough just inside the narrow peak.) The 1.65- μm brightness also shows an excess emission between $3.0R_{\odot}$ and $4.4R_{\odot}$ in the east side scans, which are $\sim 1R_{\odot}$ from the ecliptic at $4R_{\odot}$, and its intensity is considerably smaller. This suggests that the circumsolar dust cloud is a ring and not a spherical shell and is consistent with the hypothesis that the dust particles responsible for the observed infrared excess emission are identical with the interplanetary dust causing the zodiacal light—which is generally assumed to be reflected by grains as large as a few hundred micrometres, probably in orbits of high ellipticity (see, for example, ref. 13).

Finally, we can make a rough estimate of the total mass of the dust cloud in the region of infrared emission. Let us assume that the cloud is formed into a doughnut shape of mean diameter $8R_{\odot}$, radial width $1R_{\odot}$ and thickness $1R_{\odot}$, and that the rep-

resentative radius of olivine particles is 100 μm . The observed infrared fluxes measured at 1.25 and 1.65 μm will then be related, as an order of magnitude consideration, to an average number density of 1×10^{-14} particles per cm^3 and a total dust mass of 7×10^{14} g. The spatial density obtained here is about 15 times the value of simple extrapolation based on the mass density 4×10^{-23} g cm^{-3} at 1 AU (ref. 14), applying an $r^{-1.3}$ dependence on heliocentric distance.

We thank Professor H. Hasegawa for his advice and encouragement, Drs H. Tanabe, S. Isobe and T. Mukai for useful discussion, Professor J. Nishimura, Messrs H. Akiyama, Y. Koma and Y. Okabe of ISAS for their cooperation in this balloon programme, and all the staff of the balloon team of LAPAN, headed by Drs J. Soegijo and T. E. Hariadi. This research was supported by grants-in-aid for scientific research from the Ministry of Education, Science and Culture, Japan.

New model of Saturn's ionosphere with an influx of water from the rings

Current theoretical models of Saturn's ionosphere are similar to those of Jupiter's because of the gross similarity of their upper atmospheres. In the case of Jupiter, the theoretical models can be fitted reasonably well to ionospheric electron density profiles^{1,2} obtained from the Pioneer and Voyager radio occultation experiments³⁻⁵. In contrast, the theoretical models of Saturn's ionosphere are inconsistent with both the ionospheric electron density profiles^{6,7} obtained from the Pioneer and Voyager occultation observations⁸⁻¹⁰ and the large diurnal variation of maximum ionospheric electron density deduced from studies of Saturn lightning discharges^{11,12}. We propose a radically different model of Saturn's ionosphere in which water plays a major role as a minor constituent present by downward diffusion from an external source. Our model Saturn ionosphere is a classical 'F2' type layer resulting from the photodissociative production of H^+ from H_2 and rapid chemical loss by a series of charge exchange reactions with water. A planet-wide influx of $\sim 4 \times 10^7$ molecules $\text{cm}^{-2} \text{s}^{-1}$ of water from the rings is consistent with the observed ionospheric electron densities. An enhanced influx of water occurs at latitudes (-38° , $+44^\circ$) connected magnetically to the inner edge of Saturn's B ring¹² where an electromagnetic erosion process¹³ takes place. Present-day influx at these latitudes may be as large as $\sim 2 \times 10^9$ molecules $\text{cm}^{-2} \text{s}^{-1}$.

The essential features of previous theoretical models of Saturn's ionosphere are summarized below. The major topside ion, H^+ , is produced via photoionization of atomic H or photodissociative ionization of H_2 . Both H and H^+ are extremely long-lived above the homopause ($\sim 1,100$ km altitude; all altitudes referenced to the 1 bar pressure level) and are removed

Table 1 Chemical reactions in Saturn's ionosphere: H_2 , H_2O , H

	Ion production	Rate*	Ref.
A1	$\text{H}_2 + h\nu \rightarrow \text{H} + \text{H}$	$4.5 \times 10^{-10} \text{ s}^{-1}$	[7]
A2	$\text{H}_2^+ + \text{e}$	5.4×10^{-10}	[7]
A3	$\text{H} + \text{H}^+ + \text{e}$	9.5×10^{-11}	[7]
A4	$\text{H} + h\nu + \text{H}^+ + \text{e}$	7.3×10^{-10}	[7]
A5	$\text{H}_2\text{O} + h\nu \rightarrow \text{OH} + \text{H}$	1.0×10^{-7}	[19]
	$\text{OH}^+ + \text{H} + \text{e}$	5.5×10^{-10}	[19]
	$\text{H}_2 + \text{O}(^1\text{D})$	1.4×10^{-8}	[19]
	$\text{H}_2\text{O}^+ + \text{e}$	3.3×10^{-9}	[19]
	$\text{H}_2 + \text{O}^+ + \text{e}$	5.8×10^{-11}	[19]
	$\text{H}^+ + \text{OH} + \text{e}$	1.3×10^{-10}	[19]
Charge exchange/recombination			
B1	$\text{H}_2\text{O} + \text{H}^+ \rightarrow \text{H}_2\text{O}^+ + \text{H}$	$8.2 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$	[18]
B2	$\text{H}_2\text{O}^+ + \text{H}_2 \rightarrow \text{H}_3\text{O}^+ + \text{H}$	6.1×10^{-10}	[18]
B3	$\text{H}_3\text{O}^+ + \text{e} \rightarrow \text{H}_2\text{O} + \text{H}$	4.3×10^{-7}	[18]
B4	$\text{H}_2 + \text{OH}$	4.3×10^{-7}	[18]
B5	$\text{H} + \text{H} + \text{OH}$	4.3×10^{-7}	[18]
B6	$\text{H}_2^+ + \text{H}_2 \rightarrow \text{H}_3^+ + \text{H}$	2.0×10^{-9}	[7]
B7	$\text{H}_2^+ + \text{e} \rightarrow \text{H}_2 + \text{H}$	1.0×10^{-7}	[7]
B8	$\text{H}^+ + \text{e} \rightarrow \text{H} + h\nu$	2.0×10^{-12}	[7]
B9	$\text{OH} + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{H}$	3.6×10^{-11}	[18]

* Photoionization rates normalized to 10 AU by $1/R^2$ scaling of reference values.

by downward diffusion to the vicinity of the homopause where appreciable concentrations of heavier gases (most importantly methane) are encountered. H^+ ion loss occurs essentially at the homopause via charge exchange and electron-ion recombinations, resulting in a peak ion concentration of $\sim 2 \times 10^5 \text{ cm}^{-3}$ at $\sim 1,200$ km altitude. This very simplified picture emerges from a consideration of many possible chemical reactions and detailed calculations taking into account the production, diffusion and chemical losses of many atmospheric constituents⁷.

Figure 1 is a representative summary of the dawn and dusk electron density profiles (as a function of altitude) obtained from analyses of the Pioneer and Voyager radio occultation data. In Fig. 1, mid-latitude Voyager observations are compared with a typical model ionospheric electron density profile. (Figure 2 shows all of the radio science observations.) The measured electron densities are all approximately an order of magnitude less than those calculated on the basis of current models.

Maximum observed ionospheric densities are $\sim 1 \times 10^4 \text{ cm}^{-3}$, compared with a calculated maximum density of $2 \times 10^5 \text{ cm}^{-3}$ in all previous models. The peak electron density is observed at between 2,000 and 3,000 km altitude instead of the calculated 1,200 km altitude. The discrepancy in the altitude of the peak is particularly significant in light of the thermal structure of the atmosphere. Above $\sim 1,600$ km, the atmosphere is isothermal, with a temperature of ~ 800 K and an atmospheric scale height of ~ 400 km. Below that the temperature decreases linearly to ~ 125 K at 1,000 km altitude where the atmospheric scale height is ~ 60 km (ref. 7). The difference in the observed and modelled altitudes of peak ion density is thus many atmospheric scale heights. The large (~ 2 orders of magnitude) diurnal variation of maximum ionospheric electron density (Fig. 3) deduced from analyses of Saturn lightning discharges^{11,12} is even more difficult to understand on the basis of current models of Saturn's ionosphere. Without an additional loss mechanism for rapid removal of the long-lived H^+ ions, no diurnal variation is expected since the time constant for loss of H^+ above the homopause is ~ 400 h that is, many planetary rotations. This is owing to the slow electron recombination reaction $\text{H}^+ + e \rightarrow \text{H} + h\nu$ at $2 \times 10^{-12} \text{ cm}^{-3} \text{ s}^{-1}$ and the large diffusion time constant below the 2,500 km altitude of the ionospheric peak.

The observational results thus require an additional and effective loss mechanism for H^+ ions, since ion production via photodissociative ionization of H_2 and photoionization of atomic H is well understood. Several possible loss processes have been quantitatively evaluated but none has proven adequate. These include losses due to an increased methane abundance which requires an unreasonably high eddy diffusion coefficient¹⁴, removal of H^+ by vibrationally excited H_2 (ref. 6), and/or the presence of large vertical drifts^{7,8}. The possibility of an interaction between the ionosphere and ring system was recognized as early as 1975¹⁵ and a suggestion involving H^+ ion loss due to the presence of OH radicals from the rings^{16,17} was made to explain the low ionospheric densities inferred from the Pioneer observations.

We propose a simple model ionosphere dominated by the removal of H^+ ions via charge exchange with water and subsequent electron recombination. Table 1 summarizes the important chemical reactions and reaction rates; the reactions involving water have been largely drawn from work relating to comet models^{18,19}. The important reactions are H^+ ion production via dissociative photoionization of H_2 (A3) and loss via the charge exchange with H_2O (B1). The H_2O^+ ion is very short lived, reacting with H_2 (B2) to produce H_3O^+ , which is then readily removed by electron recombination (B3-B5). As in previous models, the H_2^+ ions produced by photoionization of H_2 (A2) are rapidly removed via reaction with H_2 (B6) and charge exchange (B7) and are not a major topside ion. The direct photoionization of atomic hydrogen (A4) does not significantly contribute to the H^+ ion density owing to the limited availability of atomic H.

The OH produced in B4 and B5 has a short lifetime ($\tau < 1$ s) at the altitude of the peak ion density owing to a reaction (B9) with H_2 , producing H_2O and H. Thus water acts as a catalyst in the rapid removal of H^+ ; each H^+ ion removed returns, on average, 3 or 4 H atoms with no associated chemical loss of H_2O . Photodissociation of H_2O (A5) yields OH which in the presence of appreciable H_2 (B9) rapidly reforms H_2O (as would OH from any other source). There is no net loss of water due to charge exchange or photoionization. Thus the density of water above the homopause is given by²⁰

$$N_w = N_0 \exp(-9Z/H) + FH_0/8D_0 [\exp(-Z/H) - \exp(-9Z/H)]$$

where N_0 , H_0 , and D_0 are the H_2O density, the atmospheric scale height, and molecular diffusion coefficient at a reference ($Z=0$) altitude, F is the downward flux of H_2O and H is the atmospheric scale height. Assuming that the water is readily removed by freezing out just above the homopause or by mixing

Fig. 1 Model calculations of mid-latitude ionospheric electron density as a function of altitude (extreme ultraviolet, EUV) and Voyager observations of Saturn's ionosphere at mid-latitudes, adapted from Atreya *et al.*⁷.

Fig. 2 Ionospheric electron density profiles deduced from Voyager 1 and 2 and Pioneer radio science data, adapted from Atreya *et al.*⁷. Altitude is referenced to the 1 bar pressure level.

Fig. 3 Diurnal variation of maximum ionospheric electron density inferred from Voyager observations of lightning-generated radio emissions in Saturn's atmosphere, adapted from Kaiser *et al.*¹². The dashed line indicates a model fit to the nighttime increase of maximum ionospheric electron density.

and chemical loss at the homopause, the density of water throughout the (isothermal) region of interest above 1,600 km altitude is just $N_w = (FH/8D_0) \exp(-Z/H)$. Since the diffusion coefficient $D = D_0/N$, where N is the atmospheric density, the downward flux of water results in a water density proportional to the density of the H_2 atmosphere through which it flows under the condition of constant flux, that is, $N_w/N = \text{constant} = FH/8N_0D_0$.

Under these conditions a classical 'Bradbury layer', analogous to the Earth's F2 layer can form at an altitude where the chemical τ_c and diffusive τ_d time constants are comparable^{20,21}. For such a layer, the ionospheric peak forms above the level of maximum ion production owing to the upward diffusion of ions. Below that altitude the increasing chemical loss (charge transfer with water) effectively removes the major ion, so that most of the ionization anticipated by previous models is lost. The loss coefficient is $\beta = k[H_2O]$ where k is the rate coefficient of reaction B1 in Table 1. The required water concentration at the altitude of the ionospheric peak can be estimated by $N_m \equiv q(h_m)/\beta(h_m)$ where N_m is the maximum electron density at the altitudes (h_m) of the ionospheric peak, and the ion production function q and loss β are evaluated at the altitude of the peak. Taking $h_m \sim 2,500$ km, $q \sim 1 \text{ cm}^{-3} \text{ s}^{-1}$ and $N_m \sim 10^5 \text{ cm}^{-3}$, appropriate to the equatorial ionosphere at noon, yields a water concentration of $\sim 1,250 \text{ cm}^{-3}$ at 2,500 km altitude. This requires a $4 \times 10^7 \text{ cm}^{-2} \text{ s}^{-1}$ downward flux of water molecules. The maximum densities observed at the dawn and dusk terminators where the extreme ultraviolet production rate is ~ 0.1 of the maximum are ~ 1 order of magnitude lower than the noon density, as expected. Equating the chemical and diffusive time constants ($1/\beta \sim H^2/D$) yields an expected peak altitude between 2,000 and 2,500 km.

The variation of electron density with altitude can also be understood using simple approximations to 'Bradbury layer' behaviour that have been widely used in the study of the Earth's F2 layer^{20,21}. The ion distribution well above the peak is controlled by ambipolar diffusion, so $N \sim \exp(-Z/H_p)$ where H_p is the plasma scale height. This distribution is indicated in Fig. 2 assuming 800 K electron and ion temperatures, for which $H_p = 4H$. The H^+ ion density distribution below the peak is controlled by chemical loss, with $N(h) \sim q/\beta(h)$. The ion production, q , varies slowly, so, to first approximation, we expect $N(h)$ below the peak to increase with height as $\exp(h/H)$, as is illustrated in Fig. 2. This reflects the increased loss at greater depths due to greater water concentration. The peak has a width of a few scale heights and occurs at an altitude (2,500 km) where the diffusion time constant is a few hours, as does the Earth's F2 layer. However, the rapid nighttime decay of the equatorial ionospheric density, evidenced in Fig. 3, requires a more rapid loss, perhaps a downward drift related to the ionosphere-protonosphere exchange described below.

Figure 3 shows an ionospheric density minimum just after dusk and a steady increase in near-equatorial ionospheric density throughout the night. We attribute this phenomenon to a diurnal ionosphere-protonosphere exchange similar to that proposed for the Earth's nighttime F2 layer²⁰. During daylight hours, photoproduction in Saturn's ionosphere pumps protons outward along field lines to great heights. At night, a relaxation back towards the ionosphere occurs to replenish the nighttime ionospheric density. If we assume a uniform density (n) column of protons at rest at dusk, under constant downward acceleration (a) the proton influx $\Phi_p = nat$ increases linearly with time. Supposing the nighttime maximum ionospheric density occurs at high altitudes where loss is negligible, the increase in the maximum density with time is related to the influx by $N_m(t) = \int \Phi_p/H dt = (na/2H)t^2$. This increase is indicated in Fig. 3 by the dashed line, which fits the nighttime observations well with $na/2H \sim 2 \times 10^{-5} \text{ cm}^{-3} \text{ s}^{-2}$, corresponding to a proton influx increasing to a maximum of $\sim 2 \times 10^7 \text{ cm}^{-2} \text{ s}^{-1}$ just before dawn. The equivalent ion production rate at dawn due to this exchange ($\sim 0.2 \text{ cm}^{-3} \text{ s}^{-1}$) is comparable to or greater than the extreme ultraviolet production. Thus, we envision a very dynamic ionos-

phere, characterized by ion production and transport into a vast protonosphere reservoir by day, coupled with relaxation and return by night.

The increased ion losses at latitudes connected magnetically to the inner edge of Saturn's B-ring¹² can be explained by an increased local water influx of as much as 2×10^9 molecules $\text{cm}^{-2} \text{ s}^{-1}$. The erosional process described by Northrop and Hill¹³ provides a mechanism whereby sub-micrometre charged particles (agglomeration of water molecules), unstable in Saturn's ring plane, precipitate along magnetic field lines into the ionosphere. If these particles are deposited directly at the level of the ionospheric peak ($\sim 2,500$ km) the required flux is less than $2 \times 10^9 \text{ cm}^{-2} \text{ s}^{-1}$. At this maximum flux, the ring mass loss is $\sim 6 \times 10^{-14} \text{ g cm}^{-2} \text{ s}^{-1}$. The large dayside extinction was observed at latitudes of -37 to -39° (ref. 12), the maximum southerly extent of the Voyager 1 spacecraft. Averaged over $\sim 4^\circ$ latitude extent of the presumed source region in the rings ($1.52 - 1.62 R_s$), the total ring mass loss is $\sim 1.2 \times 10^6 \text{ g s}^{-1}$ or $1.6 \times 10^{12} \text{ g yr}^{-1}$, comparable to the estimated total mass influx from interplanetary meteoroids²². At this rate, 60 g cm^{-2} of material can be removed from the source region in $\sim 30 \times 10^6$ years, suggesting that this process may be responsible for the large decrease in optical depth of the rings inward of $1.62 R_s$.

The Pioneer and Voyager observations of Saturn's ionosphere and the inferences drawn from studies of Saturn lightning can be largely understood on the basis of a new model of Saturn's ionosphere in which water plays a major role. The planetwide influx of water (4×10^7 molecules $\text{cm}^{-2} \text{ s}^{-1}$) required is approximately an order of magnitude greater than that expected from photosputtering of the rings²³. Morfill *et al.*²² estimate that micrometeorite impacts on Saturn's icy rings produce between 0.75 and $6 \times 10^6 \text{ g s}^{-1}$ of vapour, $\sim 10\%$ of which is deposited in Saturn's atmosphere. This results in an estimated influx of between 0.6 and 4.5×10^7 molecules $\text{cm}^{-2} \text{ s}^{-1}$. In spite of the uncertainties in this estimate²², micrometeorite bombardment of Saturn's rings is an attractive source mechanism because it provides an explanation of the vast differences between Jupiter's and Saturn's ionospheres. An atmospheric influx of water has been previously suggested to explain features of ultraviolet spectra of Saturn²⁴ and Voyager infrared spectra of Titan²⁵. The increased influx of water at latitudes magnetically connected to the inner edge of the B-ring is not inconsistent with expected erosion rates. Finally, we infer a diurnal ionosphere-protonosphere exchange in which protons pumped into the protonosphere by day return by night.

It is generally believed that some type of plains-forming resurfacing has continued into the recent geological past on the surfaces of the saturnian satellites, particularly Enceladus¹⁻³. In conditions of tidally-driven heating, 'magma' could emerge and produce the plains especially evident on this satellite, as well as on Tethys, Dione, and Rhea. The magma favoured at present, considering the temperatures of the satellites and their likely formation, is the peritectic melt $2\text{H}_2\text{O}\cdot\text{NH}_3$ (refs 1-4). Surprisingly, however, visible and near-IR spectra have not shown any evidence of ammonia on the optical surface of any of the satellites, although absorption bands indicative of water ice are abundantly in evidence. On the basis of laboratory-derived data on the ion erosion of water and ammonia ices, we suggest that the satellite surfaces could have become enriched with water ice over a reasonable geological time period (10^6 – 10^9 yr) owing to preferential erosion of the ammonia by magnetosphere ion bombardment. This mechanism would be an alternative explanation to other processes invoked for the absence of ammonia spectral features. The concept is similar to that of Haff⁵ who has proposed that a crust of non-volatiles could eventually coat the Galilean satellites J3 and J4 (Ganymede and Callisto) through preferential water ice erosion (an 'armouring' process).

Sputtering rates for water ice expected on the four saturnian satellites Enceladus, Tethys, Dione and Rhea, using laboratory-measured H_2O ice erosion rates⁶ and Voyager-measured ion fluxes⁷ ≥ 30 keV in the vicinity of the satellites have recently been reported⁸. These rates are shown in Table 1, together with the expected surface loss of water ice in $\text{cm } 10^{-9} \text{ yr}^{-1}$. The results are given for Voyager 2 measured particle fluxes at Enceladus (the Voyager 1 trajectory did not go in to this distance) and Voyager 1 measured fluxes at the other three moons. The rates derived from the Voyager 2 fluxes are approximately a factor of 20 less than the Voyager 1 derived values, reflecting the temporal changes in the magnetosphere plasma population. The uncertainties in the laboratory numbers are $\sim 20\%$ (ref. 6). The surface loss determination takes into account the escape fractions expected from the satellites under gravitational forces, using laboratory-determined velocity spectra for the eroded molecules⁹. (For example, 80–90% of the eroded molecules are expected to escape Enceladus.) These molecules, sputtered from the satellites as well as the E-ring, could produce the oxygen torus around the planet.^{10,11} Sputtering of the satellite surfaces by lower-energy, corotating ions may increase the rates and the erosion depths given in Table 1. In contrast, a small atmosphere or magnetic field on any of the moons would exclude lower-

energy plasma ions from striking a satellite surface. Thus, the values in Table 1 are probably a conservative estimate of the surface effect.

The values of Table 1 indicate that a surface loss of water ice ranging from a few centimetres to several metres could be expected on Enceladus, depending on the composition of the ion-flux in the vicinity of the satellite. Determinations of this composition from the Voyager 2 data suggest that there is an appreciable flux of energetic oxygen in the vicinity of Dione and Enceladus⁷. Thus, the higher values of the erosion rate and the net erosion are probably more representative of the actual situation. The erosion values for Table 1 were calculated assuming isotropic ion bombardment of the satellites, because the pitch angle anisotropies are sufficiently small in this region of the magnetosphere⁷.

We have determined in the laboratory the erosion yield Y of frozen ammonia molecules (at $\sim 10\text{K}$) under bombardment by 1.5-MeV He^+ and Ne^+ ions. These values are $Y(\text{He}^+) \sim 140$ molecules per incident ion and $Y(\text{Ne}^+) \sim 2 \times 10^3$ molecules per incident ion. At this temperature in these experiments we found no evidence for the preferential removal from the surface of the hydrogen compared with the nitrogen. However, the NH_3 could be released as atoms and/or molecules other than ammonia, as has been reported in the case of frozen NH_3 bombarded by 3-keV argon ions¹² (absolute yields are not determined in this experiment). The $Y(\text{He}^+)$ on NH_3 is comparable with those we have measured from solid oxygen and solid carbon dioxide at these temperatures, and is ~ 18 times the erosion yield on water ice (~ 8).

The detailed erosion yield studies of water ice in the laboratory show that at temperatures $\leq 100\text{K}$, for fast light ions ($\geq 1\text{keV AMU}^{-1}$), the yield varies roughly as the square of the electronic stopping power of the incident ion⁶. The ratio of the 1.5-MeV He^+ and Ne^+ erosion yields on NH_3 also varies as roughly the square of the ratio of the stopping powers. We have previously found that the erosion of water ice by heavy ions depends more steeply than quadratically on the stopping power^{6,13}. From data on heavy ions incident on H_2O ice, we have $Y(1.5\text{-MeV O}^+) \sim 650$. The stopping power of neon and oxygen are quite similar at these energies, so that we can confidently use the laboratory values for $Y(\text{Ne}^+)$ in the following.

If we assume that the molecular species in a water ice-ammonia mixture sputter at a rate proportional to the individual sputtering yields, the equilibrium concentration of ammonia is $\sim 5\%$ for light-ion (proton) irradiation to $\sim 30\%$ for only heavy-ion (oxygen) bombardment. At the higher temperatures (but $< 100\text{K}$) expected on Enceladus, the ammonia fraction will be lower as the yield for the more volatile NH_3 is expected to increase with increasing temperature. Such temperature dependencies of the yield have been observed in the range 50–90 K for CO_2 and SO_2 (ref. 6), which have material binding energies bracketing that of NH_3 . At temperatures approaching the NH_3 sublimation temperature, more volatile species, such as N_2 and H_2 , are likely to be produced¹², as in the case of sputtering of H_2O ice⁶.

As the ion bombardment enhances diffusion to the surface of the more volatile species, the layer bombarded will be depleted in nitrogen down to the penetration depth of the incident ions (~ 0.3 – $3\text{ }\mu\text{m}$ for 10 – 10^3 keV protons and a tenth that for incident O^+). In fact, much deeper layers of ammonia depletion might be expected for several reasons. Ion erosion produces a very non-uniform surface and other geological processes (such as internal heating) and exogenic processes (such as micrometeoroid gardening) can bring fresh material to the surface. Also, any ice grains from the E-ring which might coat the surface will be depleted in ammonia by ion bombardment.

Taking the values of the erosion for ammonia ice estimated above, we find that for a pure ammonia ice surface the ammonia removal on Enceladus would be some tens of centimetres (erosion by protons) to tens of metres (erosion by oxygen ions) in 10^9 yr (Table 1). Hence, in 10^9 yr , it would not be unreasonable to expect the ammonia in a frozen magma to be eroded away.

Table 1 H_2O ice erosion

Satellite	Escape flux ($10^8 \text{ H}_2\text{O cm}^{-2} \text{ s}^{-1}$)		Surface loss ($\text{m } 10^{-9} \text{ yr}^{-1}$)	
	Protons incident	Oxygen incident	Protons incident	Oxygen incident
Enceladus*	0.01	1.0	0.01	1.0
Tethys†	0.05	4.0	0.06	4.0
Dione†	0.06	5.0	0.08	6.0
Rhea†	0.02	2.0	0.02	2.0

* Voyager 2 derived numbers.

† Voyager 1 derived numbers.

leaving the surface rich in water ice. If the resurfacing of the plains of Enceladus occurred $\sim 10^6$ yr ago, although the amount of ammonia eroded would be much less, enough modification would occur to prevent the detection of ammonia in the infrared. We also note that estimates of erosion over long time periods must take into account possibilities of variations in magnetosphere fluxes. The absence of reports of detection of ammonia in the magnetosphere does not indicate the absence of ammonia and/or a nitrogen by-product. In these regions, the cold- and hot-plasma instruments could not distinguish clearly between nitrogen and oxygen. Further, nitrogen from dissociated ammonia would be indistinguishable from a nitrogen contribution from Titan's atmosphere.

A process complementary to that discussed here can result from micrometeorite impacts on the satellite surfaces. Although not discussed in detail here (micrometeoroid bombardment is reviewed in ref. 14), note that such an impact will probably be enhanced by 'gravitational focusing' around Saturn, compared with the rates expected in the heliospheric ecliptic plane (for example, on the moons of Earth and Mars). NH_3 and H_2O have vastly different vapour pressures; thus, the vaporization and

fractionization produced by micrometeoroid impact would tend to deplete the surfaces of NH_3 preferentially.

These considerations present the intriguing possibility that, under an assumption of known magnetosphere charged-particle fluxes, an estimate can be made of the lower limit of the age of the last major satellite resurfacing. Furthermore, knowledge of the ammonia erosion rate can place an upper limit on the rate of continual resurfacing of a satellite surface, if that is a viable 'tectonic' process, in contrast to sudden major occurrences of resurfacing. This coupling of geological processes with space plasma physics processes is an exciting prospect, as for the case of Io's contribution to Jupiter's heavy ion magnetosphere torus.

We thank Dr W. B. McKinnon for discussion, and other participants in the NATO Research Workshop on Ices in the Solar System, where some of these ideas were generated. We thank Dr S. Squyres for helpful comments on the first version of this paper; L.J.L. also thanks Dr D. J. Stevenson for a helpful discussion. The work at the University of Virginia was supported in part by the NSF Astronomy Division under grant No. AST-82-00477 and the NASA Geophysics/Geochemistry Division under grant NAGW-186.

Midpoint scission of macromolecules in dilute solution in turbulent flow

A. F. Horn & E. W. Merrill

Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Drag reduction by polymer additives is commonly explained in terms of nearly complete extension of the macromolecules by high extensional strain rate regions of irrotational flow associated with turbulent bursting¹⁻⁵. The intermittent nature of the bursting process means that the polymer conformation cannot be measured directly by optical methods such as light scattering or birefringence. We have studied the degradation of narrow molecular weight distribution (MWD) polystyrene in a turbulent flow device which has been carefully constructed to minimize all sources of extensional flow except for that encountered in the turbulent flow itself. We report here the results of size exclusion chromatography of the degraded samples which show that chain scission occurs in a narrow distribution around the chain midpoint, indicating that the macromolecules are highly extended when they break. This represents the most convincing evidence yet for high chain elongation of polymers in a turbulent flow.

High chain elongation has been shown to occur in model laminar extensional flows by birefringence^{2,6}. It has also been shown that laminar extensional flow induces scission of polymers in a fairly narrow distribution centred on the chain midpoint^{6,7}. Midpoint scission itself is evidence of high chain extension since the highly elongated state is the only conformation of a randomly coiling macromolecule that would cause the maximum hydrodynamic force to be at the centre of the contour length of the chain.

The degradation studies were done in a single-pass gas pressure-driven flow device (see Fig. 1 legend for a description of the device). To perform a degradation run, the degraded sample collection reservoir and flow tube were filled with pure solvent and the feed solution reservoir was filled with the polymer solution. The system was pressurized to 20-87 atm and the

Fig. 1 Schematic diagram of the turbulent flow degradation apparatus. The apparatus comprises two reservoirs of 8.9 cm ID (internal diameter) connected by a 0.70-cm ID stainless steel tube 244 cm long. The entrance to the tube from the feed solution reservoir comprises a conical funnel machined on a 4.1 cm radius that smoothly reduces the diameter from that of the reservoir to that of the tube. (This lowered by an order of magnitude the extensional strain rates caused by the entrance, and was necessary as Culter *et al.*¹⁰ have shown that entrance effects can dominate polymer degradation even in turbulent flow.) The exit from the tube to the degraded sample collection reservoir consists of a cone of 7° angle which reduces the fluid velocity by an order of magnitude. A timer-controlled solenoid valve is mounted downstream of the degraded sample collection reservoir, and solution leaving the solenoid valve is sent to a holding cylinder. A sampling valve is mounted on the degraded sample collection reservoir upstream of the solenoid valve.

solenoid valve was opened for 1.5-4 s. Polymer solution passed through the degraded sample collection reservoir and solenoid valve to the holding cylinder. While the concentration of the polymer solution changed in the degraded sample collection reservoir during the experiment, the MWD was always that of the polymer that had experienced the turbulent flow.

The molecular weight distributions of the samples were determined using size exclusion chromatography (SEC). The system consisted of a pair of Waters Ultrastaygel (10^5 Å and 10^6 Å

Fig. 2 *a*, Chromatograms of original (---) and degraded (—) 900,000-MW polystyrene. ····, 2.5 times the difference (degraded - original). *b*, Chromatograms of original (····) and degraded 3.84 × 10⁶-MW polystyrene. —, Degraded sample (single pass at 21 atm total pressure drop); ---, degraded sample (single pass at 40 atm total pressure).

pore size) columns; the plate count for the system was greater than 30,000 plates. Anionically polymerized polystyrene of molecular weight (MW) 900,000 (ratio for weight average MW to number average = 1.04 by SEC) was obtained from Pressure Chemical Co. and a sample of MW 3.84 × 10⁶ was purchased from Toyo Soda Ltd. The 3.84 × 10⁶-MW sample had a dispersity of 1.15 by SEC. The degradations were done at a polymer concentration of 50 p.p.m. in chloroform. The shear viscosity of the solution was identical to that of the pure solvent.

Figure 2*a* shows chromatograms of undegraded 900,000-MW polystyrene and the same sample after a single pass through the apparatus at 87 atm total pressure drop (Reynolds number = 730,000 and the wall shear stress was estimated as 3,000 N m⁻²). The height of the chromatogram has been normalized to simplify comparison. The degraded sample exhibits a shoulder centred at MW 450,000. When the chromatogram of the original sample is subtracted from that of the degraded sample (normalized according to peak area), the difference curve peaks at MW 450,000 (Fig. 2*a*). This proves that scission of the macromolecules occurs in a fairly narrow distribution around the chain midpoint. Midpoint scission is also confirmed by the data for the 3.84 × 10⁶-MW polymer in Fig. 2*b*. The chromatogram of the undegraded sample consists of a single peak at MW 4 × 10⁶; for the sample degraded at a system pressure drop of 21 atm, there is a shoulder at MW 4 × 10⁶ due to the unbroken fraction and a peak centred at MW 2 × 10⁶ due to the

degraded material. At 40 atm pressure drop, essentially all of the original polymer is degraded and there is a single peak centred at MW 2 × 10⁶ (Fig. 2*b*). These data are consistent with midpoint scission governed by a rate constant which decreases with decreasing molecular weight.

By using simultaneous birefringence and degradation measurements in a cross-slot flow device, Odell *et al.*⁶ have shown that midpoint scission occurs when the macromolecule is fully extended in an extensional flow. Recent SEC degradation studies done in our laboratory with a sudden contraction device confirm midpoint scission of polymer chains in extensional flow. As discussed in ref. 7, we model the extended polymer chain as a string of beads aligned with the flow to calculate the drag force on the chain. Following Zhurkov⁸, main-chain bond scission of a bond in tension is modelled as a first-order kinetic process with the rate constant given by

$$k_i = A \exp [-(E_a - F_i \Delta r) / kT] \quad (1)$$

where k_i is the first-order rate constant for scission of the i th bond, E_a is the bond energy, F_i is the force on that bond, Δr is the distance a bond must be separated to break, and k is Boltzmann's constant. Using this model, drag forces obtained from curve fitting of experimental data are of the correct order of magnitude. The width of the second peak is correctly predicted by equation (1). These results, taken in conjunction with the data of Odell *et al.*⁶, provide convincing evidence that full chain extension does indeed occur in extensional flow before chain scission and that this leads to scission centred on the chain midpoint.

Thus, the data presented here, showing midpoint scission of macromolecules in turbulent flow, strongly imply that the polymer chains can indeed be fully extended by turbulent flow, as well as by laminar extensional flow. Previous studies have suggested that scission is centred on the midpoint⁹; this notion was based primarily on the observation that the molecular weight distributions of broad MWD polymers are narrowed by degradation. The chromatograms of the degraded narrow MWD samples presented here provide the most direct evidence that we are aware of for high extension of randomly coiling macromolecules in turbulent flow.

We thank the Arco Chemical Co. for their support of this project.

Ocean-atmosphere coupling over monsoon regions

Sulochana Gadgil, P. V. Joseph* & N. V. Joshi

Indian Institute of Science, Bangalore 560 012, India

* India Meteorological Department, Pune 411 005, India

In monsoon regions, the seasonal migration of the intertropical convergence zone (ITCZ) is manifested as a seasonal reversal of winds. Most of the summer monsoon rainfall over India occurs owing to synoptic and large-scale convection associated with the continental ITCZ (Fig. 1). We have investigated the interaction between these large-scale convective systems and the ocean over which they are generated¹⁻³, concentrating on the relationship between organized convection over the Indian Ocean and sea surface temperature (SST). We report here that on a monthly basis

the degree of cloudiness correlates well with SST for the relatively colder oceans, but when SST is maintained above 28 °C it ceases to be an important factor in determining the variability of cloudiness. Over the major regions of convection east of 70° E, which are warm year after year, the observed cloudiness cannot be correlated with variations in SST.

Organized convection over the equatorial Indian Ocean has an important role in maintaining the continental ITCZ¹⁻³ (Fig. 2), and the degree of continental cloud cover is linked to that over the ocean. The most important factor governing generation and maintenance of synoptic and large-scale cloudiness in the tropics is SST^{4,5}. Variability of large-scale convection over the Pacific has been shown to be intimately related to variations in SST^{6,7}. However, the coupling between the Indian Ocean and the continental ITCZ is more complex, involving correlations between the SST and oceanic cloudiness on the one hand and the oceanic and continental cloudiness on the other.

Not surprisingly, studies of the relationship between monsoon rainfall over India and the SST anomalies over different parts of the Indian Ocean, Arabian Sea and Bay of Bengal have yielded rather low correlation values⁸⁻¹⁰. In fact, the results of these studies differ even in the sign of the correlations obtained (perhaps because the periods studied were different, or there were biases in the data, etc.). The results of different investigations of the relationship between SST anomalies over the Indian Ocean and rainfall over India using general circulation models are also ambiguous¹¹⁻¹³. The one unequivocal result of all quantitative numerical studies is the reduction (enhancement) in precipitation directly over a cold (warm) SST anomaly.

As a first step towards unravelling the complex interaction between the continental ITCZ and the SST over monsoon regions, we investigated the relationship of the synoptic and large-scale convective cloudiness over the Indian Ocean to SST during the summer monsoon.

The basic data available for 1966-72 are: (1) daily values of a cloudiness index (ranging from 1 to 9) at each 2.5° latitude-longitude square over the tropics, based on operational nephanalysis prepared by the National Environmental Satellite Service of NOAA and compiled by Sadler and associates^{14,15}, and henceforth called the Sadler index; and (2) monthly SST over the oceanic regions between 40° E and 100° E and north of 10° S for 5° latitude-longitude squares compiled by Joseph and Pillai¹⁰ from the data collected by the voluntary observing fleet of over 40 maritime nations and stored at the National Data Centre of the India Meteorological Department.

A comparison of the daily distribution of the Sadler index with the imagery of the hemispheric mosaics analysed previously in an investigation of the variation of the ITCZ over Indian longitudes², indicated that synoptic and large-scale convection (for example, ITCZ) is associated with values of ≥ 6 of the Sadler index. Thus, we have concentrated here on epochs characterized by Sadler index ≥ 6 and define the cloudiness intensity at any grid point for any month as the sum of the Sadler index for the days on which it is ≥ 6 .

Fig. 1 The ITCZ over Indian longitudes on 8 July 1973 (after ref. 1).

Fig. 2 Variation of the location and latitudinal extent of the ITCZ at 90° E during the monsoon seasons of 1973-75.

For a 5° grid, there are 58 squares (cells) in our study region for which SST and cloudiness intensity are given for each month (June-September) of 1966-1972. This corresponds to over 1,600 cell-months for the seven monsoon seasons. The distribution of these cell-months in the SST cloudiness intensity plane is shown in Fig. 3. The most remarkable feature of this distribution is the restriction of the points to the warmer side of the lines *ab*, *bc*. A given level of cloudiness intensity occurs only if the SST is higher than a specific value, which is clearly a necessary condition for occurrence of organized convection. For SST below 28 °C there is a well defined value for the maximum cloudiness intensity (which increases linearly with SST), whereas above 28 °C it seems to become independent of SST, although there are too few points with large cloudiness intensities to make definitive statements about this behaviour. Up to about 28 °C, the minimum cloudiness intensity is zero (that is, a Sadler index of < 6 for each day of the month) but above 28 °C it increases with SST. The probability of occurrence of different cloudiness intensities for a given SST also shows a marked change across 28 °C (Fig. 4). Whereas the most probable intensity is zero below 28 °C, it abruptly shifts to ~ 40 units above this SST. These results suggest that a SST of 28 °C is the threshold for active generation of organized convection.

Table 1 Correlation between SST and degree of cloudiness over Indian Ocean

SST greater than (°C)	No. of data points	Correlation coefficient ($\pm 95\%$ confidence limits)
24.5	1,602	0.564 ± 0.034
25.0	1,568	0.548 ± 0.035
25.5	1,502	0.517 ± 0.037
26	1,418	0.468 ± 0.041
26.5	1,340	0.418 ± 0.045
27	1,212	0.364 ± 0.050
27.5	1,064	0.282 ± 0.056
28	823	0.183 ± 0.067
28.5	468	0.094 ± 0.092
29	190	0.01

Fig. 3 Cloudiness intensity plotted against SST for June–September 1966–1972. The number of cell-months at each location is indicated: •, 1–4; ●, 5–9; ●, >10.

Fig. 4 The percentage of cell-months with different cloudiness intensities for SST in the given 1°C interval.

The probability of occurrence of cloudiness of 60 units (that is, about 10 'cloudy' days per month) is zero for SST below 26.5°C, which is the Palmen¹⁶ threshold for tropical cyclogenesis. This probability increases with SST, reaching a value of 0.65 (and not unity) over the warmest waters, which demonstrates clearly that high SST is a necessary but not sufficient condition for sustained cloudiness over a significant portion of the month.

The correlation between SST and cloudiness intensity based on the entire summer data set is large and positive: 0.566 ± 0.033 (95% confidence limits). Most of this correlation arises from restriction of the cloudy region to relatively warm waters, and once the threshold of 28°C is crossed, the intensity of cloud cover is no longer dependent on the SST (as seen in Table 1 for the correlation coefficient for restricted data sets comprising only cells with SST above the specified limit). Of the many factors that are important for intense convection such as lower tropospheric convergence, SST, etc., SST ceases to be the critical limiting factor when maintained above the threshold. Thus, over the warm oceans¹⁷ east of 70°E, which are the major regions of organized convection, the correlation is poor (and over some parts even negative). In fact, the observed variability in cloudiness during 1966–72 over the north Indian Ocean cannot be attributed to the variation of the monthly SST.

1,700-Myr greenstone volcanic successions in southwestern North America and isotopic evolution of Proterozoic mantle

Bruce K. Nelson & Donald J. DePaolo

Department of Earth and Space Sciences, University of California, Los Angeles, California 90024, USA

The formation of continental crust over the past 3,800 Myr has depleted the mantle of large-ion lithophile elements¹. A knowledge of the timing of the depletion and the degree of chemical homogeneity of the depleted mantle over the history of the Earth is important to understand the development of the continents, their recycling back into the mantle^{2–6}, and the nature of convection and mixing in the ancient mantle. This may be inferred by determining the initial $^{143}\text{Nd}/^{144}\text{Nd}$, $^{176}\text{Hf}/^{177}\text{Hf}$, and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of igneous rocks that were derived from the mantle at various times. Initial $^{143}\text{Nd}/^{144}\text{Nd}$ ratios of ~1,700-Myr greenstones from the Rocky Mountains range from $\epsilon_{\text{Nd}} = +3.3$ to $+6.5$, the highest values yet observed for mid-Proterozoic rocks. These data constrain the change in ϵ_{Nd} of depleted mantle to be only 2–3 ϵ units over the past ~1,700 Myr which supports the hypothesis of significant recycling of continental crust into the mantle^{2,3}.

Nd and Sr isotopic data were collected from ~1,700-Myr old metavolcanic rocks along a 750-km long traverse from near the Wyoming Archaean province to central New Mexico (Fig. 1). These predominantly mafic oceanic volcanic rocks probably represent primitive island-arc type magmatic effusions which are believed to be the raw materials for the generation of continental crust⁷. Lack of evidence for crust older than 1,800 Myr (ref. 8), and trace element data^{8–10} suggest that the samples are not significantly contaminated by older crust. The objectives of analysing this suite are to determine the Nd and Sr isotopic composition of the mantle 1,700 Myr ago, and to assess the meaning of the isotopic data for the evolution of the upper mantle and for the petrogenesis of these and other rocks of similar ages^{11,12}.

The volcanic greenstone successions sampled are summarized in Table 1. The U–Pb (zircon) crystallization ages for these rocks increase from south to north towards the Archaean craton (Fig. 1) (refs 13–15, 18 and S. Bowring, in preparation). The samples from the Green Mountain Formation were collected from within 3 km south of the Wyoming Shear Zone^{17–18}, which separates the ≤1,800 Myr-old crust from the >2,500 Myr Archaean province to the North.

The analytical methods are described elsewhere^{19,20}, except that neodymium isotopic measurements were made using an NdO⁺ ion beam rather than Nd⁺. Dissolution procedures are detailed in Table 1.

The Sm–Nd and Rb–Sr isotopic data are listed in Table 1. The initial ϵ_{Nd} and ϵ_{Sr} values of the samples have been calculated

Table 1 Rb-Sr and Sm-Nd isotopic data on greenstone belts, southwestern USA

* Calculated with respect to a chondritic reservoir with composition today of $^{143}\text{Nd}/^{144}\text{Nd} = 0.511836$, $^{147}\text{Sm}/^{144}\text{Nd} = 0.1967$, $\lambda_{\text{Sm}} = 0.00654 \times 10^{-3} \text{ Myr}^{-1}$. Error for calculated initial Nd ratio is $\pm 0.5 \epsilon$ units. The initial $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{87}\text{Sr}/^{86}\text{Sr}$ ratios have been converted to ϵ_{Nd} and ϵ_{Sr} values, which indicate how the ratios differ from those expected for primitive mantle reservoirs at the time of formation of the lavas^{28,36}.

$$\epsilon_{\text{Nd}} = 10^4 \left[\frac{^{143}\text{Nd}/^{144}\text{Nd}_{\text{rock}}}{^{143}\text{Nd}/^{144}\text{Nd}_{\text{CHUR}}} - 1 \right]$$

† Uncertainties at the 95% confidence level. $^{143}\text{Nd}/^{144}\text{Nd}$ normalized to $^{146}\text{Nd}/^{142}\text{Nd} = 0.636151$, $^{87}\text{Sr}/^{86}\text{Sr}$ normalized to $^{86}\text{Sr}/^{88}\text{Sr} = 0.1194$.

‡ Calculated with respect to a uniform reservoir with present composition of $^{87}\text{Sr}/^{86}\text{Sr} = 0.7045$, $^{87}\text{Rb}/^{86}\text{Sr} = 0.0827$, $\lambda_{\text{Sr}} = 0.0142 \times 10^{-3} \text{ Myr}^{-1}$. Error for calculated initial Sr ratio is $\pm 0.5 \epsilon$ units for low Rb/Sr to ± 0.9 for high Rb/Sr.

§ These rhyolites were spiked and then dissolved in sealed Teflon bombs at 180 °C for 7 days. A second aliquot of each rhyolite was also completely dissolved in Teflon beakers for comparison (second entry). The small differences observed are within the range expected for sample heterogeneity (for example, see two aliquots of 79-18-26) and the calculated initial isotopic ratios are the same within analytical uncertainty.

using the zircon U-Pb ages (Table 1, Figs 2, 3). All of the initial ϵ_{Nd} values are positive. The Green Mountain Formation (GMF) has values of +3 to +4, which are comparable with those determined previously for the Twilight Gneiss and the Idaho Springs Formation orthogneiss¹¹. The ϵ_{Nd} values for the Dubois and Tijeras greenstones are in the range +4.5 to +6.5, which are the highest values yet measured on any rocks of this general age^{21,22} (Fig. 2). The basaltic rocks of the Pecos greenstones have ϵ_{Nd} values that are similar to those of the GMF. One ultramafic sample (79-18-26), however, has ϵ_{Nd} as high as +6.9, although this sample could be especially susceptible to post-crystallization disturbance because of its low Nd content. A second ultramafic sample (79-23-26) collected only 300 m from the first has a calculated initial ϵ_{Nd} of +4.5, which is more consistent with values measured for the Pecos basalts.

Because small amounts of crustal contamination would cause the ϵ_{Nd} values of magmas to be lowered, we infer that the highest ϵ_{Nd} values measured are most likely to be representative of the upper-mantle. The other rock suites may be affected by minor involvement of preexisting Archaean crust, which would have had an average ϵ_{Nd} value of about -10 (Fig. 4). The samples with the lowest ϵ_{Nd} values occur closest to the Archaean craton, which is qualitatively consistent with the contamination hypothesis. However, a wide variety of rock types from a fairly broad area all seem to have been affected to the same extent (GMF, Pecos, Idaho Springs Formation and the Twilight Gneiss). This implies that there was a rather effective and large-scale process of crust-mantle mixing involved. Only a small proportion of crust is necessary to explain the shift from $\epsilon_{\text{Nd}} = +6$ to $\epsilon_{\text{Nd}} = +4$ (1-5% depending on the process), so even the most 'contaminated' rocks still largely represent primitive mantle-derived materials.

The relatively high initial ϵ_{Nd} values of up to +6.5 (or +6.9) have important implications for crust-mantle evolution models^{3,5,6}. The relationship between these data and data on island-arc type mafic volcanic rocks of other ages is illustrated in Fig. 2. The data suggest that the ϵ_{Nd} value of the depleted mantle source of continental-type materials has increased by only about 2 or 3 ϵ units over the past 1,800 Myr. The growth of ϵ_{Nd} expected for *in situ* radioactive decay in the mantle is given by: $Q_{\text{Nd}} f_{\text{Sm}/\text{Nd}}$ (ref. 3) where Q_{Nd} is $25.13 \times 10^{-3} \text{ Myr}^{-1}$ and $f_{\text{Sm}/\text{Nd}}$ is the Sm/Nd enrichment factor relative to chondrites. The highest $f_{\text{Sm}/\text{Nd}}$ value measured on a 1,700 Myr greenstone (MZ-6) of +0.20 is similar to the highest values measured on young mid-ocean ridge basalts (MORB)²³. Based on partial melting models, the $f_{\text{Sm}/\text{Nd}}$ value of the mantle source should be larger¹. Consequently, the growth rate of ϵ_{Nd} in the mantle due to *in situ* radioactive decay is expected to be $> 5 \times 10^{-3} \text{ Myr}^{-1}$, or ~3-5 times faster than observed. These data verify the discrepancy noted previously³ and emphasize the need to have low- ϵ_{Nd} materials injected into the mantle, to slow the growth of the upper mantle ϵ_{Nd} value. We believe that this low- ϵ_{Nd} material is old continental crust, although other explanations have been proposed²⁴. The data also constrain the depleted mantle curve for mid-Proterozoic time to significantly higher ϵ_{Nd} values than previously suggested^{11,25} (Fig. 2).

Poor correlation of measured $^{87}\text{Rb}/^{86}\text{Sr}$ with $^{87}\text{Sr}/^{86}\text{Sr}$ (Table 1) indicates disturbance of the Rb-Sr systematics of the samples. This casts doubt on their reliability as estimators of the mantle $^{87}\text{Sr}/^{86}\text{Sr}$ value. The calculated initial values for the samples are compared with present-day oceanic basalt values on the $\epsilon_{\text{Nd}} - \epsilon_{\text{Sr}}$ diagram^{30,31} (Fig. 3). This representation assumes that the present-day whole Earth $^{87}\text{Sr}/^{86}\text{Sr}$ and $^{87}\text{Rb}/^{86}\text{Sr}$ ratios are 0.7045 and 0.0827 respectively²⁶. The ϵ_{Sr} values for the Proterozoic

Fig. 1 Precambrian outcrop map of Wyoming, Colorado and New Mexico, USA showing sample locations and U-Pb ages from zircons (adapted from ref. 8).

Fig. 2 Nd isotopic evolution diagram for the depleted mantle. Data from this work are shown in solid rectangles. (1), Tijeras; (2), Dubois; (3), Green Mountain Formation, which corresponds to the range for the Colorado Front Range¹¹ (CFR), (4a) Pecos, (4b) possibly altered ultramafic sample from Pecos. Large arrow indicates average evolution for Archaean crust^{37,38}. Other isotopic data: K, Kambalda³⁹; CS, Cape Smith²¹; SA, Saudi Arabia⁴⁰; B, Bay of Islands ophiolite²⁹; S, Samail ophiolite⁴¹. A histogram of published ϵ_{Nd} values for modern intra-oceanic island arcs apparently free from contamination by older crust is shown at left^{28,42-50}. All samples with $\epsilon_{Nd} < 6.5$ are either boninites or from the Lesser Antilles. Dashed curve (labelled DM) is isotopic evolution of depleted mantle proposed by DePaolo¹¹ and Allègre and Rousseau²⁵.

Fig. 3 ϵ_{Nd} versus ϵ_{Sr} diagram, showing initial ratios calculated for samples with $^{87}Rb/^{86}Sr < 0.1$ (●) and $^{87}Rb/^{86}Sr > 0.1$ (■). (Data that plot outside range of graph are indicated by arrows with ϵ_{Sr} values.) Oceanic correlation line for modern basalts corresponds to $\epsilon_{Sr} = -2.7\epsilon_{Nd}$. Value and estimated errors for bulk Earth isotopic composition are from ref. 26. Depleted mantle should always have values along the correlation line (see text). Three samples plot near this line, but typically the Rb-Sr systems have been strongly disturbed by later metamorphic or weathering events.

metabasalts with $^{87}Rb/^{86}Sr < 0.1$ appear to be too high relative to their ϵ_{Nd} values when compared with young oceanic lavas, especially those from mid-ocean ridges^{23,26,27}. All except three of the samples plot to the right of the line $\epsilon_{Sr} = -2.7\epsilon_{Nd}$. The three anomalous samples have impossibly low calculated initial ϵ_{Sr} values and are clearly disturbed. Three of the samples with higher $^{87}Rb/^{86}Sr$ ratios lie close to the line. The apparent shift of ϵ_{Sr} values to the right on the diagram is similar to altered young oceanic basalts and some island-arc lavas²⁶⁻²⁹. This, and the relatively large range of observed ϵ_{Sr} values lead us to conclude that the samples do not precisely define the ϵ_{Sr} value of the mantle sources of the lavas. Most simple models of mantle isotopic evolution predict that the ϵ_{Sr} value of depleted mantle reservoirs should lie near the MORB-whole Earth line for all time. This follows from the observation that the partitioning of Sr and Nd between the mantle and the continental crust may be similar³⁰, though this has not been proven. ϵ_{Nd} values of +6 should correspond to $\epsilon_{Sr} = -16$ or $^{87}Sr/^{86}Sr \approx 0.7014$ at ~1,700 Myr ago. Most previous studies of mid-Proterozoic rocks have failed to find initial $^{87}Rb/^{86}Sr$ values this low^{21,31}. Our data are consistent with this low value for the mantle, but cannot be considered proof because of the uncertainties associated with

the effects of metamorphism. We emphasize that the observed initial $^{87}Rb/^{86}Sr$ ratios in the high-Rb/Sr rocks (as low as 0.7023) would normally be considered to be quite low, but the correct mantle value is probably lower.

Greenstones of 1,680–1,780 Myr age in the southern Rocky Mountains have high ϵ_{Nd} values and high Sm/Nd ratios that indicate the existence of relatively homogenous and widespread depleted mantle reservoirs similar to those sampled today in oceanic magmatic arcs. The data strengthen the observation³

that the growth of ε_{Nd} in the upper mantle has been retarded over the past 2,000 Myr, probably because of recycling of continental crust. The general tendency for samples nearer the Archaean craton to have lower initial ε_{Nd} values argues for contamination with small amounts of Archaean crust. Yet these samples—the GMF, Twilight Gneiss and Idaho Springs Formation—all have the same calculated initial $\varepsilon_{Nd} = 3.7 \pm 0.5$, which implies vigorous and thorough regional mixing of a small amount of crust into the mantle near the Archaean plate boundary. The almost ubiquitous disturbance of the Rb-Sr system in crustal rocks makes it difficult to determine a precise $^{87}Sr/^{86}Sr$ evolution curve for depleted mantle. Continuing efforts to establish this curve are, however, extremely important in the context of establishing the history of crust-mantle evolution.

The Nd data confirm earlier conclusions that large segments of the crust in southwestern North America were derived from the mantle ~1,800 Myr ago³². Compared with the Mesozoic and Cenozoic patterns, this suggests major contrasts in rates, and possibly styles, of plate tectonics in middle Proterozoic time³³.

We thank Kent Condie and James Robertson for providing well documented samples, Sam Bowring for discussions of regional geology, and P. J. Patchett for reviewing the manuscript. This work was supported by a grant from donors of the Petroleum Research Fund, administered by the American Chemical Society, and NSF grant EAR82-12377.

A mechanism for magmatic accretion under spreading centres

John A. Whitehead Jr, Henry J. B. Dick & Hans Schouten

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

The most active volcanic zone on Earth occurs along the global mid-ocean ridge system where the lithosphere is pulled apart and new oceanic crust is created at rates between 10 and 200 km Myr⁻¹. This volcanism is segmented, and is concentrated along the axial valleys and highs of slow- and fast-spreading ridges respectively, with transform fault zones separating, and generally offsetting, each active ridge segment. Volcanic activity may be nearly absent at the ridge transform intersection where a slow-spreading ridge is offset, and greatly reduced where a fast-spreading ridge is offset, implying thinner crust in these regions¹. The source of magmas erupted along ocean ridges is the underlying mantle, which undergoes decompression melting when rising to fill the gap between the spreading plates. The resulting magma aggregates in the upper mantle and ascends to the crust due to its low density compared with the parent mantle rock. The melt is believed to pool in crustal magma chambers—whence it periodically erupts to the surface. Typically, the formation, ascent and aggregation of magmas along the mid-ocean ridges is regarded two-dimensionally and modelled in a section through the crust and mantle across the strike of the ridges (see ref. 2). Here, however, we consider the problem with a three-dimensional model for which we provide supporting geological evidence, in which the magmas rise as a result of a gravitational instability (modified Rayleigh-Taylor) in the underlying partial melt zone.

It is reasonable, to a first approximation, to assume that the mantle is behaving as a viscous newtonian fluid, so we can expect the upwelling to be two dimensional with a maximum under the smoothed location of the spreading centre. If this is the case, we also postulate that a linear region of high-melt content exists in the mantle below the ridge where melt aggregates from the rising asthenosphere. This region could be approximated as a horizontal cylindrical body with relatively low viscosity and density compared with the overlying mantle. In such circumstances, it will develop a gravitational instability leading to regularly spaced vertical protrusions. We have conducted some simple experiments in which a water-glycerine mixture was quickly injected into glycerine along a horizontal line. Although this line will gradually rise because the water-glycerine mixture is less dense than the pure glycerine, an instability will always also develop as shown in Fig. 1 and lead to semi-spherical pockets. It is reasonable to expect that a linear

Fig. 1 Gravitational instability of a horizontal line of water/glycerine mixture in a bath of pure glycerine. Kinematic viscosity of the glycerine is estimated as $5.0 \text{ cm}^2 \text{ s}^{-1}$, that of the water/glycerine mixture as $0.015 \text{ cm}^2 \text{ s}^{-1}$, and reduced gravity $g^* = g\Delta\rho/\rho = 260 \text{ cm s}^{-2}$. The dark stripe at the bottom is 0.64 cm diameter tubing, and the initial diameter of the conduit is estimated with a precision optical micrometer to range from 0.16 to 0.24 cm. The spacing of the 25 diapirs in *d* is 39.5 cm for an average of 1.6-cm spacing, giving a ratio of spacing to conduit diameter of 7–10. Marsh argues that the formula for spacing is $d/D = 2\pi/2.15 (\mu_1/\mu_2)^{1/3}$, where μ_1 is viscosity of the upper fluid and μ_2 is viscosity of the conduit fluid with perhaps an order one correction in the coefficient⁴. Our parameter group $2\pi/2.15 (\mu_1/\mu_2)^{1/3}$ is ~ 20 , roughly twice as big, but well within the acceptable range given.

region of partially molten mantle in the Earth will behave in a similar manner and will lead to fairly regularly spaced protrusions from which the melt will ascend to form magma chambers at spreading ridges.

The instability is similar to the classical Rayleigh–Taylor instability in fluid mechanics. It occurs when there is a density inversion, that is a layer of heavy fluid over light. Whitehead and Luther³ reported some experiments and theory on this instability which were relevant when both viscosities were large. They found that the ratio of the wavelength of fastest-growing disturbances to the thickness of the unstable layer was large as the viscosity contrast became large. Thus, a thin layer of relatively low-viscosity fluid can be expected to develop very widely spaced protrusions. Marsh^{4,5} isolated a similar problem, the instability of a ribbon-like, or cylindrical (with its axis horizontal), body of low-viscosity material. The ribbon-like region was produced in the laboratory by allowing black oil or glycerine to rise from a slit in the bottom of a container of glycerine. Marsh suggests that this diapir-genesis occurs under island arcs and is the mechanism that leads to the formation of the magma chambers for the island-arc volcanoes. Noting the regular spacing of magmatic centres across Iceland, Sigurdsson and Sparks⁶ suggest that a similar instability exists at the base of the lithosphere in Iceland.

The suggestion that there is convection at right angles to the direction of relative plate movement is not new (see ref. 7). However, we suggest that an instability due to density change through melting in the mantle beneath the ridge produces upwellings with length scales of the spacing between the midpoints of spreading centre segments. This also implies that axial magma chambers are localized at the midpoints of individual ridge segments.

Fig. 2 Viscous asthenosphere rises two-dimensionally beneath the boundary between two spreading lithospheric plates. The lithosphere thickens away from the spreading boundary (dashed lines). Above a certain level (dotted lines), the rising asthenosphere passes through a zone in which partial melt can form which collects at some level below the base of the lithosphere. Due to its lower viscosity and density, the partial-melt zone develops a gravitational instability leading to regularly spaced concentrations of melt which rise to the surface to form crustal magma chambers. The asthenosphere, effectively depleted by this process, must continue to rise viscously and on cooling become lithosphere. The wavelength of the gravitational instability (and the subsequent spacing of spreading centres or transform zones) should also depend on the width of the partial melt zone which is expected to be proportional to the spreading rate.

Evidence for a partially molten zone beneath the base of the lithosphere is seen from regional magnetotelluric measurements in Iceland. These measurements indicate an anomalous conducting layer at a depth of 8–15 km beneath the Neovolcanic Zone which is interpreted as a partially molten zone near the top of the mantle⁸. This zone may correspond to the partially molten region we require in the mantle beneath mid-ocean ridges.

Direct evidence for melt accumulation from a partially molten zone beneath the mid-ocean ridges can be seen in plagioclase-bearing peridotites from oceanic fracture zones. These rocks constitute $\sim 30\%$ of dredged abyssal peridotites⁹ and generally contain $<0.5\%$ interstitial plagioclase which is believed to have largely crystallized from trapped melt^{10–12}. Given the proportion of plagioclase in primitive abyssal tholeiite, it represents $<1\%$ trapped melt in the peridotites, although in rare cases, as locally along the Romanche Fracture Zone, peridotites from one or more dredge haul contain an average of $\geq 6\%$ plagioclase⁹ corresponding to $\sim 13\%$ trapped melt. This is direct evidence for local accumulation of melt in the mantle, which we believe is the result of a Rayleigh–Taylor instability in the partially molten zone and a rapid migration of melt towards the resulting protrusions into the overlying mantle. Green and Hibberson¹³ studied the stability of plagioclase in peridotites at high pressures and found that it was unstable at pressures >8.5 kbar. Based on these phase relations, the zone of melt aggregation represented by the plagioclase-peridotites must lie at <25 km in the mantle.

Abyssal peridotites dredged largely from oceanic fracture zones are generally accepted as the residues of mantle melting which generated abyssal basalts. Almost 70% of these peridotites are plagioclase-free spinel peridotites⁹. Table 1 compares their average composition with independent estimates of undepleted upper mantle composition and a typical primitive abyssal basalt. This shows that melting of the upper mantle would rapidly deplete the solid residue in those elements which occur in far greater abundance in basalt than in the postulated source rock. From the relative concentrations of CaO and Al_2O_3 in Table 1, somewhere between 15 and 20% melt would have to be removed from the postulated parents to produce the observed concentrations of these oxides in the fracture zone peridotites.

Taking all abyssal peridotites together gives an average of 0.9% plagioclase which would correspond to ~1–2% trapped melt. Thus most of the melt which was formed in peridotites dredged from fracture zones must have been drained off. Most of these rocks, however, were dredged from regions in fracture zones where only peridotites were exposed for areas of hundreds, if not thousands, of square kilometres and where little, if any, basalt exists. Accordingly, the melts were not emplaced in the same region as their parental peridotites. We propose that melt formed at depth near fracture zones migrates laterally through the mantle towards an upwelling beneath the centre of the ridge segment rather than that the depleted peridotites were emplaced laterally into the fracture zone after melting beneath the ridge.

Figure 2 summarizes our suggested structure and flow field. The asthenosphere rises viscously beneath the spreading centres. Above a certain level, the rising asthenosphere enters a zone in which partial melt can form. To a first approximation the viscous flow of the asthenosphere is two-dimensional with its axis parallel to the ridge. Thus the rate of partial melt formation is nearly uniform below the ridge axis. The partially molten zone will have relatively low viscosity and density compared with the overlying mantle. The partially molten zone thus develops regularly spaced protrusions centred beneath individual ridge segments. The melt, which can migrate by porous flow, may move more rapidly than the partially molten layer as a whole and concentrate at the tops of the rising protrusions. This would lead to gravitational separation of melt from the mantle and its ascent to form or feed crustal magma chambers. Above the melt aggregation zone, the depleted asthenosphere must continue to rise viscously and, on cooling, become lithosphere.

Young melt concentrations will replenish the older crustal magma chambers. New crust is formed by crystallization of gabbro along the margins of the magma chambers, by the injection of dykes from the magma chambers into the existing crust, both laterally and vertically along the spreading centre axes, and by extrusion of pillow basalts and massive flows from magma chambers and dykes to the top of the crust. Furthest away from the crustal magma chambers, that is, in the transform zones between spreading centres, fewer dykes will be injected and accordingly fewer pillow basalts and massive flows will be extruded, thus producing thinner crust.

This model provides an explanation for the regular segmentation of ocean ridges. Schouten and Klitgord¹⁴ postulated that the sea floor in the slow-spreading North Atlantic (and in other oceans) was formed in a relatively stationary series of spreading centre cells separated by transform-fault zones. From Mesozoic marine magnetic anomalies (155–108 Myr ago) in the western North Atlantic, they estimate a typical separation between spreading centre cells of the order of 50 km, similar to the present distribution of axial valleys on the Mid-Atlantic Ridge. The magnitude of offset between adjacent spreading centres is typically <30 km, can change with time, and can even go through zero and change sign¹⁵. This is inconsistent with an offset-generating mechanism inferred from the rheology of the plate material alone, as the ridges should lose their 'memory' of the fracture zone at 'zero offset'. The stability of spreading centre cells, then appears independent of offsets between them^{14–16}. The model proposed here predicts regular segmentation of ocean ridges, particularly where no large-offset transforms exist. The model also predicts that the crust at small and zero-offset fracture zones should thin, which is consistent with what little is known from seismic studies of these features^{15,17–19}.

Lateral flow of melt towards regularly-spaced protrusions centred beneath individual ridge segments would inhibit flow and mixing of melt in the mantle between ridge segments. Accordingly, melts erupted at each ridge segment will be derived largely from the mantle beneath that segment. This provides a simple explanation for the geochemical discontinuities observed in ridge basalts across fracture zones (see ref. 20) and strongly supports a laterally heterogeneous oceanic mantle. This effect is heightened at large-offset fracture zones where old-cold lithosphere, juxtaposed against the rising asthenosphere, depresses

the partially molten zone¹ and produces a substantial physical barrier to the lateral flow of magmas. We note that our model does not rule out segregation and intrusion of melt to the crust from greater depths in the mantle, nor does it rule out the occurrence of secondary instabilities in the partially molten layer either near fracture zones or laterally away from the ridge axis. We point out, however, that it does predict the presence of geochemical discontinuities in ridge basalts even at zero-offset fracture zones.

This paper developed from a series of interdisciplinary seminars and direct research support sponsored by the Center for the Analysis of Marine Systems of the Woods Hole Oceanographic Institution with funds provided by the Exxon Education Foundation. Anaerobic consumption of organic matter in modern marine sediments

A. Yu. Lein

Institute of Biochemistry and Physiology of Microorganisms, USSR Academy of Sciences, Pushino, Moscow Region, 142292, USSR

Previous estimates of the global organic carbon (C_{org}) budget have generally considered the anaerobic consumption of C_{org} to be of minor importance. Data for the rates of bacterial sulphate reduction in various morphological zones of the oceans indicate, however, that approximately 14% of the total C_{org} reaching the sediment-water interface is consumed by anaerobic processes. Of this, some 70% is taken up in sediments on the continental shelves and slopes in water depths of less than 1,000 m. Although this represents only a small fraction of the global primary carbon productivity, it may have important consequences for models of the carbon and sulphur cycles.

There is some controversy over the rate of primary productivity in the world ocean. Values ranging from 20 Gton $C yr^{-1}$ (refs 1, 2) to 126 Gton $C yr^{-1}$ (ref. 3) have been reported. In view of recent work which questions the validity of the ^{14}C -technique⁴ and considers contributions from picoplank-

Table 1 C_{org} budget for the top 1 m section of shelf sediments off Mexico (Station 668, depth 140 m, 23°23'N, 106°56'9W)

	C_{org} flux
Primary production in the region	$2.5 \text{ g m}^{-2} \text{ d}^{-1}$ ($= 0.91 \text{ kg m}^{-2} \text{ yr}^{-1}$)
C_{org} flux to sea floor (15% of primary production) ¹⁰	$0.14 \text{ kg m}^{-2} \text{ yr}^{-1}$
C_{org} consumption for bacterial sulphate reduction at the rate of $55.7 \mu\text{g S per kg sediment per day}$ (ref. 16)	$41.8 \mu\text{g C per kg sediment per day}$ $22.9 \text{ g C m}^{-2} \text{ yr}^{-1}$ ($= 229 \text{ kg C m}^{-2} \text{ per } 10^4 \text{ yr}$)
Thus, C_{org} consumption for anaerobic bacterial sulphate reduction	
Residual C_{org} (top 1 m) at 3% C_{org} and 60% water	18 kg C m^{-2}
C_{org} consumption for aerobic respiration for the top 1 m at O_2 consumption of $10 \text{ mol m}^{-2} \text{ d}^{-1}$	$1,168 \text{ kg C per m}^{-2} \text{ per } 10^4 \text{ yr}$
Hence the total C_{org} consumption in the uppermost metre of sediment ($229 + 18 + 1,168$) = $1,415 \text{ kg C m}^{-2} \text{ per } 10^4 \text{ yr}$.	

The rate of sedimentation is 10 cm kyr^{-1} (ref. 24), thus 1 m is assumed to have been deposited in 10^4 yr . The wet density is 1.5 g cm^{-3} and this is therefore equivalent to $1,500 \text{ kg m}^{-2}$.

ton^{5,6}, chemo- autotrophic⁷ and lithotrophic bacteria⁸, Riley's³ higher value seems the more realistic. Mineralization in the euphotic zone by grazers or chemical oxidation recycles ~60–80% of the particulate organic matter (POM) and, depending on water depth, all or none of its will reach the sea floor.

The POM which ultimately reaches the sediment–water interface will partly be remineralized in the benthic layer⁹ or through the action of burrowing organisms and microbes. It has been estimated that 527,109 moles O_2 are consumed daily in marine sediments¹⁰. This allows POM consumption figures for aerobic processes in bottom sediments to be derived assuming the reaction

to be a reasonable approximation. This yields a value for POM consumption of $2,308 \text{ Gton C yr}^{-1}$.

However, anaerobic processes are also at work in marine sediments and I have attempted to estimate the anaerobic C_{org} remineralization in recent marine sediments.

One way of calculating the anaerobic remineralization of POM is to use the difference in C_{org} or N_{org} values between the top and bottom sections of piston cores and take the resulting decay rate for the two compounds as a measure of anaerobic respiration of POM¹¹. This method, however, has great limitations because even the top sediment layers retrieved in the core material may already contain some biologically inert POM and furthermore, rates of sedimentation may vary considerably between the top and the bottom of the core.

Another approach, which utilizes C_{org} consumption rates, is based on the reduction of manganese, iron and sulphur compounds; estimates of respiration are obtained according to a formula developed by Upsensky and Strakhova^{12–15}. In principle, C_{org} consumption is related to the generation of certain solid phases such as pyrite, but the POM consumed when other oxidized species are reduced, is neglected. Strakhov¹⁵ was the first to draw attention to this oversight. He pointed out that additional factors control POM utilization in marine sediments, such as the release of COOH , CH_4 or NH_3 .

Recent biogeochemical findings suggest that not all H_2S generated by reduction of sulphate will enter a solid phase. Some H_2S will migrate upwards or become oxidized. Figure 1 depicts the relationships between various oxidized and reduced sulphur species encountered in representative sediment cores from the Pacific^{15,16}. Sulphate in interstitial water is highly enriched in ^{32}S , with $\delta^{34}\text{S}$ values in the range of +15.6 to +18.8‰, compared with a $\delta^{34}\text{S}$ value of +20‰ for seawater sulphate. This indicates that the sub-surface sulphate maximum (Fig. 1) is caused by the oxidation of isotopically-light metabolic H_2S rather than by a conservative uptake of seawater sulphate during deposition. Analysis of all three forms of sulphur, that is gaseous, dissolved and solid, from anaerobic sediments of Limfjord, Denmark¹⁷ reveals that only 10% of the H_2S generated *in situ* is associated with sulphides and disulphides. The remaining 90% diffuses from shallow muds to near bottom water or on oxidation becomes part of the general sulphur cycle in sediments. From these few but representative examples, it is inferred that reduced sediments, especially those generating free H_2S remineralize more C_{org} during anaerobic microbial early diagenesis than would be expected from the amount of pyrite or other sulphur-containing minerals that are present. These apparent shortcomings can be overcome by using radioactive sulphur- and carbon-isotope techniques to trace and quantify C_{org} remineralization in anoxic sediments^{16–18}.

Bacterial sulphate reduction accounts for 90–95% of the anaerobic remineralized POM^{19,20}. Thus to estimate C_{org} consumption in conditions of anaerobic diagenesis it is sufficient to know the rate at which bacterial sulphate is reduced in sediments. Sulphate reduction can briefly be summarized as follows:

(that is 1 mole S oxidizes 2 moles C) which is a quantitative expression of anaerobic remineralization.

Quantitative data on sulphate reduction in the open sea, in marine sediments, and that obtained in laboratory conditions using radioactive isotope tracer techniques agree very well. Therefore, it is possible to calculate rates of microbial activities for the top metre of modern oceanic sediments and to evaluate C_{org} consumption in conditions of early diagenesis in anoxic media^{11,17,19–21}. In a few instances, knowledge of sedimentation

Table 2 Estimates of global bacterial sulphate reduction in the uppermost metre of oceanic sediments

Geomorphological zone	Depth (m)	Area (10^6 km^2)	Intensity of sulphate reduction ($\mu\text{g S kg}^{-1} \text{ d}^{-1}$) (mg S $\text{kg}^{-1} \text{ yr}^{-1}$)		Productivity of sulphate reduction (g S $\text{m}^{-2} \text{ yr}^{-1}$)	Flux of $\Sigma \text{H}_2\text{S}$ ($10^6 \text{ tons yr}^{-1}$)	C_{org} consumption for sulphate reduction ($10^6 \text{ tons C yr}^{-1}$)	(%)
Shelf	0–50	11(2)	55.6	20.3	26.4	79.2	59.5	16
	50–200	16(3)	37.3	13.6	17.7	53.1	40.0	11

	1,000–3,000	(61)	5.5	2.0	2.6	158.6	119.2	32
Foot of slopes, depressions, oceanic bed	>3,000	257	0.97	0.35	—	—	—	—
Total		360 (81)				491.9	369.7	100

Estimates are after refs 16, 18, 20, 21, 25, 26. The figures in parentheses give the areas of biogeochemically active sediments with bacterial sulphate reduction.

Fig. 1 Depth distribution (in cm) of dissolved sulphur species in pore waters of anoxic oceanic sediments. For location of stations and further details see ref. 24.

rates and the rate of bacterial sulphate reduction (from ^{35}S tracer techniques) allows the calculation of C_{org} budgets. Table 1 summarizes the data for shelf sediments off Mexico. In brief, $\sim 1,400 \text{ kg } C_{\text{org}} \text{ per m}^2 \text{ per } 10^4 \text{ yr}$ enter the marine sediments, of which $<20\%$ are consumed by anaerobic processes. There is a close correspondence between the estimates of C_{org} flux to the sea floor and the total C_{org} consumption during diagenesis.

Experimental data from about 30 stations are compiled in Table 2. This data set covers all critical morphometric zones of the world ocean^{16,17,20,21} and reveals mean global reduction rates for the upper 1 m of the surface sediment layer. About 70% of the total C_{org} consumed anaerobically occurs in sediments down to water depths of 1,000 m. The annual production of metabolic H_2S per square metre sediment of sediment and C_{org} consumed for this process were calculated from the data on the reduction intensity. C_{org} consumption for anaerobic bacterial processes in diagenesis makes up nearly 14% of the total C_{org} arriving at the world ocean bottom (Table 3).

Table 3 Global oceanic C_{org} budget

Process	$10^6 \text{ tons yr}^{-1}$	%
C_{org} consumption:		
aerobic ¹⁰	2,308	83
anaerobic	370	14
C_{org} buried ¹⁶	85	3
Total C_{org} flux to the bottom	2,763	100

Although the above conclusions are reached using comparatively few data points, the global validity of the suggested approach appears to be more meaningful and realistic than pathways taken by previous investigators^{11-15,22,23}. This is because not only solid mineral phases but also a wide variety of gaseous and soluble metabolic products have been considered in the present quantification of anaerobic bacterial processes operating in modern marine sediments.

Long tree-ring chronologies provide a unique calendrical record that is of value for archaeological dating, climatic and post-glacial studies. They also form a standard for the calibration of the radiocarbon time scale. The world's longest continuous tree-ring chronology is based on the bristlecone pine (*Pinus aristata* and *Pinus longaeva*) growing in the White Mountains of California¹⁻³. The great age of living and sub-fossil trees of this species enabled a continuous tree-ring sequence of 8,681 years to be established, providing absolutely dated wood samples for the first radiocarbon calibration^{4,5}. We have now established an unbroken west European tree-ring sequence spanning the past 7,272 years.

Figure 1 shows the areas from which the samples are derived. The deciduous oaks (*Quercus petraea* and *Quercus robur*) used for both the German and Irish tree-ring studies show several marked differences from the bristlecone pines. They all grew at low altitude ($<200 \text{ m}$ in Ireland and $<400 \text{ m}$ in Germany, compared with $\sim 3,000 \text{ m}$ for the bristlecone pines), with average life spans of only 150-250 yr compared with 1,000 yr or more for bristlecone pines. Hence, the establishment of this long oak chronology required the linking together of a great number of tree-ring records by the process of cross-dating.

Fig. 1 Map to show the origin of oaks that contributed to the European oak chronology. Area A (north of Ireland), mostly bog oaks; area B (northern Germany), bog oaks and archaeological timbers; area C, southern Germany, mostly river valley oaks. The star indicates the site of Swan Carr in eastern England.

The synchronism of sequences of tree-ring widths is determined by visual and statistical comparison of the patterns of wide and narrow rings. The average growth increment for each year, derived from a number of trees, forms the tree-ring chronology. In both Ireland and Germany, individual ring patterns were cross-dated and merged to form site chronologies. The chronology building process consisted of linking those internally consistent site chronologies, typically of 500–1,000 yr length, to form even longer floating chronologies^{6–8}. Eventually these long floating chronologies were linked to the sequences from living trees to form an absolute time scale. By 1982, a continuous sequence existed in Germany extending back 4,000 yr⁸ (recently extended to 6,000 yr⁹), and in Ireland there was a potential sequence extending back 7,200 yr from the present, with only a single gap between 200 and 13 BC and 13 BC¹⁰.

There is no theoretical basis for judging the geographical distance over which cross-dating will be feasible, so attempts to cross-date the Irish and German sequences were based on previous empirical experience. Successful stepwise cross-dating has been achieved in a west-east transect from eastern France to eastern Austria¹¹, in a north-south direction from Swiss lake dwellings to the south German valleys^{12–14} and up to the southern coastal area of the Baltic Sea^{8,15,16}. It has also been shown that cross-dating is possible from Ireland to Germany by stepwise comparison of chronologies from Ireland to England to Germany^{17,18}. For example, in the modern era, sections of English chronology can be dated to the same calendar year against both the independent Irish and German chronologies. In attempting to establish cross-dating directly between Irish and

German oak chronologies, one must bear in mind the differences in climatic and ecological conditions. For example, the Irish and north German bog oaks had a different hydrological environment from the river valley oaks of southern Germany and from the dry land oaks used in archaeological sites. However, in spite of these ecological differences and the considerable distances involved, the statistical significance and consistency of the cross-dating is sufficient to ensure that both chronologies are exactly synchronized.

Reliable cross-dating between the north of Ireland and northern Germany for the second millennium BC was established in early 1982 and appeared to place a long floating section of Irish chronology into the exact time span 5218–158 BC. However, by mid-1982, work on timbers from the Roman site at Carlisle in northern England and from Iron Age sites at Navan and Dorsey in Northern Ireland had established a tentative link between the absolute chronologies of the AD era and the young end of the Irish sub-fossil chronology. This specified the end date of the floating Irish sequence as 229 BC instead of 158 BC, as suggested by the link with German chronologies. Baillie¹⁰ pointed out that the dating of the entire German chronology complex earlier than 550 BC was dependent on timbers from a single site, Kirnsulzbach, dated by Hollstein¹⁹. The chronology from this site, which has had its own dendrochronological problems²⁰, seems to have been incorrectly placed. It is now agreed that the German sequence must be broken at 550 BC and the chronology before 550 BC moved back by 71 yr. Once this has been done, consistent cross-dating can be demonstrated between Ireland and Germany at all time periods back to 3000 BC.

A closer look at the critical links within the master chronologies reveals that within the corrected Hollstein chronology there is an overlap of only 33 yr (546–514 BC) and in the south German master chronology an overlap of only 7 yr (546–540 BC). Such overlaps could in themselves never be used as significant links. The weakest link in the Irish sequence is at 250 BC. Here the long floating sequence is linked to the absolute chronology by the Navan-Dorsey series, with overlaps of 130 and 133 yr, respectively. Thus, only by replication between chronologies from the three areas of Ireland, north Germany and south Germany, can final proof of the entire European chronology be provided.

After the German chronology had been broken at 550 BC and the older section moved back by 71 yr, three analyses were carried out to test the replication between the Irish and the corrected German chronologies. The first used the *t*-test²¹ over all the critical overlaps between north Germany and Ireland (Fig. 2). The *t*-test applied here is a rather crude routine test widely accepted as a valuable aid in cross-dating rather than a rigorous statistical test¹⁷. In this program, the correlation coefficient is calculated on the logs of high-pass filtered series and *t* calculated from this. The values of *t* cannot be converted to probabilities because allowance is not made for autocorrelation. The significance of the test in the present study is that in

Fig. 2 Critical links between chronologies from Ireland, England, north and south Germany over the period AD 500 to 1200 BC showing the weak link at 550 BC in the German sequence and at 250 BC in the Irish sequence. The numbers shown beside the links are *t*-values calculated according to Baillie and Pilcher²¹. The unpublished Southwark chronology was provided by Dr I. Tyers. The West German chronology is from Hollstein¹⁹.

all but one of the cases illustrated in Fig. 2 (the exception being Navan-Dorsey and Southwark), the t -value quoted is the highest value for all possible positions of overlap of the two series. The t -test should be seen as complementing the visual cross-dating.

In addition to the t -test, the percentage of parallel variation, GL% (Gleichlaufigkeits value²²), provides a powerful test of synchrony when used on long time series. This simple non-parametric test derives the first differences of the two series and then determines what percentage of the total common years of the two series has the same sign. A test of the south German chronology against the Irish chronology over a total of 4,700 yr gave a GL% of 54.0%, significant at the 99.99% level. If the 1,582 signature years in the south German chronology are tested against the same years in the Irish sequence, the GL% rises to 56.1%, again significant at the 99.99% level. The Irish sequence and the three north German sequences give GL% values of 57.0, 56.8 and 55.6%, all significant at the 99.99% level.

A third confirmatory test was carried out between the Irish and the north and south German chronologies. The long chronologies were split into 400-yr sub-periods, each staggered by 100 yr, and tested using the GL% test. Consistent values (all significant at least at the 95% level, many at 99.99%) were obtained over the entire period from 2000 BC to AD 500. As these correlations are maintained across the weak links at 550 BC and 250 BC, it is possible to claim that a fully replicated European chronology complex exists back to the third millennium BC. The Irish chronology is continuous and internally replicated back to 5289 BC.

Having established on tree-ring grounds that the German chronologies before 550 BC must be moved back by 71 yr, the observed discrepancy between the radiocarbon measurements on bristlecone pine and German oak, found to be between 69 and 72 yr²³, can now be explained. The construction of over 7,000 yr of European tree-ring chronology means that all of the radiocarbon calibration measurements on European oak are now anchored to a calendrical time scale and can be compared directly with measurements on bristlecone pine. The high precision results reported by the Belfast laboratory in 1983 used this time scale^{25,26}. The other implications of the completion of such long sequences of tree rings have yet to be assessed. An increasing number of archaeological sites, particularly in central Europe, can now be given definitive calendrical dates¹²⁻¹⁴. Extension of the European chronology further into the early post-glacial is currently under investigation, and there is a possibility of further replication using another German oak chronology established at the Göttingen laboratory²⁴. The long tree-ring sequences clearly have potential for long-term palaeoclimatic studies not only by palaeoecological²⁷ and climatological^{28,29} interpretation of their growth patterns, but also by their use for radiocarbon³⁰ and stable isotope studies³¹.

We thank the Science and Engineering Research Council for support of the British Isles tree-ring work.

Diuretic and smooth muscle-relaxing peptides, designated atrial natriuretic peptides (ANPs), have been identified in human¹⁻³ and rat⁴⁻¹⁰ atrial tissues and implicated in the control of fluid volume and vascular function^{11,12}. Recently, cDNAs encoding the human² and rat¹³⁻¹⁵ ANP precursors have been sequenced. We previously isolated from human tissue a natriuretic peptide of molecular weight (MW) 13,000 (γ -hANP) comprising 126 amino acid residues, the largest natriuretic peptide so far identified, and showed that it is directly derived from the 151-residue human ANP precursor by the removal of a signal peptide^{2,3}. We now report the isolation and sequence analysis of a novel rat atrial natriuretic peptide (γ -rANP) of MW 13,000, which derives from the rat ANP precursor. We also report the molecular cloning and nucleotide sequence analysis of the cDNA of the 152-residue rat ANP precursor, which is remarkably similar to the human 151-residue precursor (pre-hANP) except at the C-terminus. Differences in the rat and human precursor nucleotide sequences around the termination codons lead to a difference in processing pattern.

γ -rANP was purified from a side fraction isolated previously^{6,9} using an assay for relaxant activity in chick rectum¹². Early in the purification procedure, the γ -component of MW 13,000 was separated from other lower-molecular weight components on the basis of its weaker basicity by batchwise chromatography on SP-Sephadex C-25 of rat atrial extracts^{6,9}. Gel filtration of the γ -component on Sephadex G-75 yielded crude γ -rANP as a major peak of rectum-relaxing activity eluting in fractions 41-47, corresponding to a molecular weight of ~13,000 (Fig. 1a). Subsequent reverse-phase HPLC yielded purified γ -rANP, a 126-amino acid peptide with similar but less potent natriuretic activity than lower-molecular weight α -rANP⁹ and β -rANP⁶. The yield from 258 rat atria (52.5 g), estimated from amino acid analysis, was 115 nmol which is surprisingly higher than those of smaller rANPs^{6,9} (~1-2 nmol each in the present purification), indicating that γ -rANP is the major natriuretic peptide in rat atria.

Sequence analyses of the disulphide-linked γ -rANP were performed after converting to the reduced and S-carboxymethylated (RCM-) derivative. Direct Edman degradation of the purified RCM- γ -rANP identified the N-terminal sequence (1-41, Fig. 2). The C-terminal sequence of the RCM- γ -rANP, verified by carboxypeptidase digestion^{1,3,6}, was Ser-Phe-Arg-Tyr, which is identical to those of the rANPs so far identified,

Fig. 1 *a*, Gel filtration of fraction SP-II, derived from rat atrial extracts on a calibrated column of Sephadex G-75 (1.8×135 cm; flow rate 10 ml h⁻¹; eluent, 1 M AcOH; fraction size, 5 ml per tube). Relative relaxant activity in chick rectum is indicated by black bars. *b*, Reverse-phase HPLC of purified γ -rANP (1.25 nmol). Column: TSK LS-410 ODS SIL (4×250 mm; ToyoSoda). Solvent system: linear gradient elution from (A) to (B) for 80 min; flow rate 1 ml min⁻¹; H₂O/CH₃CN/10% trifluoroacetic acid (TFA) = 90:10:1 (A) and 40:60:1 (B) (v/v). *c*, Reverse-phase HPLC of tryptic digests derived from RCM- γ -rANP (2.5 nmol). For trypsinization conditions see Fig. 2 legend. Column: Chemcosorb 3 ODS-H (4.6×75 mm; Chemco). Solvent system: linear gradient elution from (A) to (B) for 60 min; flow rate 1 ml min⁻¹; H₂O/CH₃CN/10% TFA = 100:0:1 (A) and 40:60:1 (B) (v/v). Tryptic peptides, designated as T, are numbered sequentially in the order in which they occur in γ -rANP (see Fig. 2). T1' is identical to T1, except that Met residue is oxidized.

Methods: The starting material used was a side fraction, referred to as the γ -component of rectum activity corresponding to MW ~13,000, which was obtained in our previous purification of α - and β -rANP^{6,9}. Rat atrial tissue (52.5 g) was extracted from 258 rats and treated as described previously^{6,9} to collect the fraction corresponding to MW <15,000. After lyophilization, dry material was dissolved in 1 M AcOH, then subjected to batchwise chromatography on SP-Sephadex C-25 (H⁺-form), pre-equilibrated with 1 M AcOH. Successive elutions with 1 M AcOH, 2 M pyridine and 2 M pyridine-AcOH (pH 5.0) yielded three fractions: SP-I, SP-II and SP-III. The γ -component was eluted in fraction SP-II, while the α - and β -components eluted in fraction SP-III. SP-II obtained in this manner was the starting material for purification of γ -rANP. Gel filtration of SP-II was performed on a column of Sephadex G-75. An aliquot from each fraction was bioassayed for relaxant activity in chick rectum (*a*). Fractions 41–47 eliciting the rectum activity were subjected to preparative HPLC on a reverse-phase column of TSK LS-410 ODS SIL (8.0×250 mm; ToyoSoda) and rechromatographed. The purity of γ -rANP obtained in this manner was checked by further reverse-phase HPLC (*b*). Bioassay was performed as follows. Chick rectum relaxant activity of the sample was assayed at 37 °C as described elsewhere^{1,12}, using strips of freshly isolated chick rectum. Muscle tone was induced in the rectum strips by adding 2×10^{-8} M carbamyl choline. Natriuretic and diuretic activities after injection into rats were assayed elsewhere^{1,11}. Three observations were made for each dose.

Fig. 2 Complete amino acid sequence of γ -rANP. Sequence analyses were performed with RCM- γ -rANP and a series of tryptic peptide fragments (designated as T). S-carboxymethylation of γ -rANP was achieved by reduction with 50 mM dithiothreitol (DTT) in 0.5 M Tris-HCl buffer (pH 8.5) for 4 h at 37 °C, followed by reaction with 100 mM iodoacetate for 5 min. The resulting RCM- γ -rANP was purified by reverse-phase HPLC. Carboxy-terminal analysis of RCM- γ -rANP (1.0 nmol) was performed by successive digestion with carboxypeptidase A and B (100 ng each; Sigma) in a buffer of 0.2 M N-ethylmorpholine acetate (pH 8.0) at 37 °C. Amino acids released at appropriate time intervals were analysed at the picomole level with a pre-fluorescence labelling analysis system (Waters)^{1,6,9}. RCM- γ -rANP (2 nmol) was digested with 2 μ g of trypsin (tosylphenylethylchloromethyl ketone-treated; Worthington) in 25 μ l of 1% ammonium bicarbonate (pH 8.0) at 37 °C for 3 h. Tryptic peptides were separated by reverse-phase HPLC (Fig. 1c). Sequence analyses of RCM- γ -rANP and its tryptic peptides were performed by stepwise Edman degradation, using a gas-phase automated sequencer (Applied Biosystems 470A), coupled with HPLC identification of the resulting PTH-amino acids.

implying that γ -rANP represents an N-terminally elongated form of the known rANPs.

Further structural information was provided by analysing tryptic peptides derived from RCM- γ -rANP, which were separated by reverse-phase HPLC (Fig. 1c). Overlapping of the sequences of tryptic peptides with the N-terminal (1–41) sequence determined above and the known sequences of 73- (ref. 7) and 48-residue⁶ rANPs made it possible to establish

unambiguously the complete amino acid sequence of γ -rANP (Fig. 2).

We have also cloned and sequenced cDNAs encoding γ -rANP, as described in Fig. 3 legend. Briefly, the hANP cDNA insert which we had previously isolated and analysed was ³²P-labelled by nick-translation and used as a probe for screening a cDNA library constructed from atrial poly(A)⁺ RNA of Wistar Kyoto rats. The nucleotide sequence of plasmid prANP10 which

Fig. 3 Sequencing strategy for the cDNA insert of prANP10. The restriction map shows only those restriction sites relevant to the present work; they are identified by numbers indicating the 5'-terminal nucleotides generated by cleavage. □, Sequence corresponding to coding region; ■, coding region for putative signal peptide. Nucleotides are numbered as in Fig. 4. The direction and extent of sequence determination are shown by arrows (→, upper strand; ←, lower strand). The sites of 5'-end-labelling are indicated by the short vertical lines at the ends of arrows. Slash marks mean that 5'-end-labelling was done on the site located on the vector DNA. Vertical dotted lines mean that the transcription primed by the general primers was started from the sites located on the pUC8 plasmid.

Methods: A cDNA library was constructed by the method of Okayama and Berg²² from 4.2 µg of the vector-primer and 20 µg of poly(A)⁺ RNA isolated from 100 atria of Wistar Kyoto rats as before. Approximately 10,000 transformants of *Escherichia coli* WA802 were obtained from ~1.7 µg of the original poly(A)⁺ RNA; these were screened by hybridization²³ with ³²P-labelled probe at 65 °C for 16 h. The probe was prepared from a 463-bp *EcoRI*-*PstI* fragment of the cDNA insert of phANP82 which had been cloned from a library of cDNA of human atrial total poly(A)⁺ RNA as described previously³. Positive clones were submitted to cleared lysate analysis^{3,24}, and we confirmed that the three clones (prANP10, 11 and 12) which had a long cDNA insert contained the α-rANP coding sequence by hybridizing with tetradecamer pools (oligo I and II), representing all possible complementary sequences corresponding to α-hANP(12-16), which were used to probe cloned cDNA encoding the human precursor³. The plasmid prANP10 was used for further sequencing as described previously³: a, Maxam-Gilbert method²⁵; b, method of Sanger *et al.*²⁴, after cloning three fragments of the insert (*PstI*-*HincII*-*PstI* and *PstI*-*PvuII*, generated by digestion with *PstI* and *PvuII* endonucleases) into plasmid pUC8. (The Okayama-Berg primer-vector carries *PstI* and *PvuII* sites.)

Fig. 4 Nucleotide and deduced amino acid sequences of the cDNA for pre-rANP, compared with those of pre-hANP cDNA³. The nucleotide sequence of prANP10 was determined as described in Fig. 3 legend; the predicted amino acid sequence is shown under the nucleotide sequence. The nucleotide and amino acid sequences of the pre-hANP cDNA³ are shown above those of the pre-rANP cDNA for comparison. Nucleotide residues are numbered (Roman type) in the 5' to 3' direction, beginning with the first residue of the ATG triplet encoding the initiating methionine. Nucleotides 5' of residue 1 are indicated by negative numbers. Amino acids are numbered in italics starting from the initiating methionine and the N-terminal residues of γ-ANPs; S before the number denotes the putative signal sequence. Sequences are aligned to give maximum homology with the introduction of minimal deletions. Deletions are indicated by short horizontal lines on a one-to-one basis. Identical amino acids and the triplets encoding them are boxed; identical nucleotides are marked by +. Asterisks above or below nucleotides of untranslated regions are marker nucleotides. The broken line at the top indicates a sequence which has no thymidylate residues; horizontal arrows indicate direct repeats. Vertical arrows labelled with Greek letters indicate cutting sites used to generate the respective ANP subclasses. AATAAA sequences are underlined. Poly(A) stretches and their approximate chain lengths are shown by (A) and suffixes.

had the longest insert (782 base pairs (bp), excluding the poly(A) sequence), was found to contain the entire coding sequence for γ-rANP (Fig. 4). The N-terminal 24 amino acids of the rat ANP precursor (pre-rANP), share characteristic features with the signal sequences generally found in presecretory proteins^{16,17}. It has many hydrophobic amino acids, indeed residues S10-S19 are all hydrophobic, forming a hydrophobic core¹⁸. The apparent cleavage site for signal peptidase is after residue 24, alanine, which often occurs before cleavage sites for other signal peptidases¹⁸. The sequence encoding γ-rANP of 126 amino acid residues, immediately follows the putative signal peptide sequence and ends at residue 150, a tyrosine (amino acid 126), which is connected to the extra C-terminal Arg-Arg sequence. Note that in pre-hANP, translational termination occurs just after the last residue, a tyrosine. Interestingly, 15 nucleotides downstream, the codon for the C-terminal tyrosine of pre-hANP (position 126) is identical to that of pre-rANP, except for a single base replacement at the first nucleotide, which converts the termination codon TGA in pre-hANP to the codon for Arg in pre-rANP. Thus, translation of pre-rANP continues two amino acid residues beyond Tyr 126 and ends at the other termination triplet, TAA. The absence from rat atrial extracts

of the peptides that terminate in the Arg-Arg sequence suggests that the C-terminal Arg-Arg is removed from the 152-residue precursor at an earlier stage after synthesis to produce γ-rANP of 126 amino acids. The difference is not due to an error during reverse transcription because the sequence of another plasmid (prANP12), which is shorter than that of prANP10, was found to have the same sequence.

The human ANP precursor contains no glycosylation sites¹⁹. In contrast, the rat precursor contains the tripeptide sequence Asn-Pro-Ser, which is regarded as a possible glycosylation site, at positions 63-65 (Fig. 2). However, no glycosylation at Asn 63 was detected in γ-rANP.

There is remarkable homology between the human and rat γ-ANPs in both the nucleotide (85.2%) and amino acid (86.5%) sequences. The amino acid sequences of the putative signal peptides are only 52% homologous, while nucleotide sequence homology is 70.7% if the precursor sequences shown in Fig. 4 are aligned to allow maximum homology. The 5'- and 3'-untranslated regions are very similar. The eight nucleotides upstream of the initiator codons are identical, including the A in position -3 (ref. 20), and the 15 residues downstream from the codons for tyrosine 126 are the same except for the one base as discussed

above. The pre-rANP cDNA sequence has two AATAAA sequences, which precede poly(A) addition sites in many eukaryotic mRNAs²¹, 4 nucleotides apart, whereas the pre-hANP sequence has only one, in the long sequence shared by both precursors. The poly(A) stretch starts immediately after this sequence in the case of pre-rANP, and 5 nucleotides after in the case of pre-hANP. In the 5'-noncoding region of the pre-hANP cDNA insert, GGAACCAGAG sequences are repeated only one nucleotide apart in a long thymidylate-minus sequence. AACCAGAG is also present in pre-rANP cDNA at similar sites, but whether it is repeated or not is unclear because of the apparent incomplete reverse transcription of the mRNA.

Despite the remarkable structural similarities between the

human and rat ANP precursors, their processing is strikingly different. In the human, only three distinct ANPs, α - (28 residues), β - (56 residues) and γ -hANP (126 residues), have been identified¹⁻³. In rat atrial tissue, however, a variety of low- and intermediate-size natriuretic polypeptides (73, 48, 35, 33, 32, 31, 28, 25, 23 and 21 amino acids long) varying in the length of N-terminal extension, has been identified⁴⁻⁹, although in very low yields. The difference in processing patterns may be a result of the amino acid differences between the rat and human γ -ANPs, which may change their conformation and therefore their susceptibility to the proteolytic enzymes, or, more likely, a result of a difference in the enzymatic systems responsible for the processing.

Electron microscopic autoradiographic localization of opioid receptors in rat neostriatum

Edith Hamel* & Alain Beaudet

Laboratory of Neuroanatomy, Montreal Neurological Institute, 3801 University Street, Montreal, Quebec, Canada H3A 2B4

The regional distribution of opioid receptors in the mammalian central nervous system has been extensively studied by light microscopic autoradiography¹⁻³. Little is known, however, about the fine structural localization of these receptor sites apart from the fact that they are present in both synaptosomal and smooth microsomal subcellular fractions of whole brain homogenates⁴⁻⁶. Previously^{7,8}, using the Met-enkephalin analogue FK 33-824 (Sandoz)⁹, we determined that brain opioid binding sites could be visualized by electron microscopic autoradiography. We now report on the ultrastructural distribution of these sites in the caudate-putamen of the rat. The vast majority of specifically labelled opioid binding sites were found to be associated with axo-dendritic (53%), axo-axonic (18%) or axo-somatic (3%) neuronal membrane interfaces. Only 7%, however, were associated with synaptic junctions. These results suggest that opioids act primarily at non-junctional interfaces on the dendrites, axons and soma of neurones in the neostriatum.

Opioid binding sites in rat brain were labelled *in vitro*, using the monoiodinated opioid pentapeptide agonist FK 33-824 (¹²⁵I-FK)⁸ (see Fig. 1 legend). Film autoradiographs from sections incubated with ¹²⁵I-FK alone revealed a patch-like distribution of bound ligand molecules similar to that previously reported for opioid receptors in rat neostriatum^{10,11} (total binding; Fig. 1a). In contrast, sections incubated in the presence of 1 μ M naloxone showed sparse and homogeneous labelling (non-specific binding; Fig. 1b). Both radioactivity measurements and grain counts performed in light microscopic autoradiographs yielded ratios of specific over total binding of the order of 80%.

In electron microscope autoradiographs from sections incubated with ¹²⁵I-FK alone, most of the silver grains (65.3%) were

found by 50% probability circle analysis^{12,13} to be associated with two or more juxtaposed neuronal elements. Radioactive sources were ascribed by 'line source' analysis¹³ to the apposed plasma membranes (70% of the grains within one half distance of the membranes in a sample of 100 shared grains). However, because of limitations inherent to the autoradiographic technique, it was not possible to determine whether radioactive sources were linked to a particular apposed membrane, or to cell surface rather than to internal membrane components. In sections incubated in the presence of 1 μ M naloxone, silver grains were found predominantly over single neuronal structures and their overall distribution was significantly different from that of total binding. The ultrastructural distribution of speci-

Table 1 Ultrastructural distribution of real and hypothetical grains in autoradiographs from ¹²⁵I-FK-labelled striatal sections

Included within a 50% probability circle	Real (specific) (%)	Hypothetical (%)
Single structures		
Nerve cell bodies	13.1 $\pm$ 1.4	23.3
Axon terminals	1.5 $\pm$ 0.5	12.1
Dendrites	5.9 $\pm$ 3.1	18.7
Apposed structures		
Axon/dendrite:		
Non-junctional	45.8 $\pm$ 3.7	13.0
Junctional	7.1 $\pm$ 0.5	3.1
Axon/axon	17.6 $\pm$ 1.3	9.2
Axon/soma	3.2 $\pm$ 1.1	1.0
Dendrite/dendrite	1.9 $\pm$ 0.5	6.1
Others	3.9 $\pm$ 0.8	13.5
No. of grains counted	1,961	10,039

The distribution of specifically bound ¹²⁵I-FK molecules (real grains) was derived from grain counts performed in sections incubated with ¹²⁵I-FK alone. Values were corrected for nonspecific binding according to the distribution of silver grains in sections incubated in the presence of 1 μ M naloxone. The data are expressed as the mean $\pm$ s.e.m. of five different experiments. Silver grains were ascribed to underlying cellular constituents using a 50% probability circle (diameter = 3.4 $\times$ half distance (HD); HD = 90 nm)¹³. The uniform distribution pattern (hypothetical grains) was generated by means of a transparent overlay displaying a regular array of resolution circles. A χ^2 analysis showed the two distributions to be significantly different with $P \leq 0.005$.

* Present address: Laboratoires d'Etudes et de Recherches Synthelabo, 31, avenue P.V.-Couturier, Bagneux F-92220, France.

Fig. 1 Film autoradiographs of 75 μm -thick pre-fixed, vibratome-cut sections from rat neostriatum incubated with 1 nM ^{125}I -FK in the absence (total binding, *a*) or the presence (nonspecific binding, *b*) of 1 μM naloxone, fixed in glutaraldehyde, post-fixed in OsO_4 and dehydrated in ethanol. The distribution of total binding (*a*) conforms with that previously reported for opioid binding sites within the same region^{10,11}. Note the patches of high labelling density in the caudate-putamen (CP) as well as the moderate to strong reactivity of the nucleus accumbens (A) and of the deeper half of layer VI in the cingulate cortex (CC). Nonspecific labelling in the same area (*b*) appears weak and homogeneous by comparison. $\times 7$.

Methods: Adult male Sprague-Dawley rats (150–200 g) were anaesthetized with pentobarbital and perfused for 15–20 min through the ascending aorta with ice-cold 0.1 M phosphate buffer containing 1% tannic acid, 0.75% paraformaldehyde and 0.1% glutaraldehyde. The brains were rapidly removed and serial 70–75 μm -thick sections of the caudoputamen were cut in ice-cold 0.12 M phosphate buffer using a vibrating microtome (Vibratome; Oxford Co.). These sections were incubated with 1 nM monoiodinated ^{125}I -FK 33-824 (100–150 Ci mmol^{-1}) in 0.05 M Tris-HCl containing 0.25 M sucrose pH 7.4, for 30 min at room temperature. The labelled sections were then rinsed twice in cold buffer, fixed with 4% glutaraldehyde, post-fixed in 2% osmium tetroxide and dehydrated in ethanol. This fixation/dehydration sequence was shown to ensure regionally proportional retention of >50% of the bound radioactivity⁸. After dehydration, the sections were placed in a γ counter for determination of the bound radioactivity and either autoradiographed whole using LKB Ultrafilm or flat-embedded in Epon for light and electron microscopic autoradiography. To assess the proportion and distribution of nonspecific binding, some of the sections were incubated with ^{125}I -FK as above, but in the presence of 1 μM naloxone or non-radioactive FK. Specific binding was defined as the difference between total and nonspecific binding. Projection of film autoradiographs over camera lucida drawings of adjacent Epon-embedded sections allowed precise sampling of receptor-dense areas for high-resolution studies. For light microscopic autoradiography, semi-thin (1 μm -thick) sections were taken from the surface of each block and coated by dipping into Kodak NTB-2 nuclear emulsion. For electron microscopic autoradiography, silver-gold sections were cut from the same blocks, collected on parlodion-subbed slides, double-stained with uranyl acetate and lead citrate, sprayed with carbon and coated with Ilford L-4 emulsion diluted 1:4.

cally bound ^{125}I -FK was in turn significantly different from that of uniformly distributed hypothetical grains (Table 1).

Fifty-three per cent of silver grains corresponding to specifically bound ^{125}I -FK molecules were associated with axo-dendritic interfaces (Table 1). Such interfaces were characterized by a close apposition of axonal and dendritic membranes without intervening glial processes (Fig. 2*a, b*). Axonal elements corresponded in most instances to small varicosities (0.75 μm in mean diameter) containing numerous small, round, electron-lucent vesicles (Fig. 2*a, b*) and occasional large granular vesicles. Their dendritic counterparts were mainly shafts of medium to small calibre (Fig. 2*a, b*), but also comprised proximal trunks and spines. In most instances (45.8% of grains counted; Table 1), no synaptic differentiation was present within the resolution circle (Fig. 2*a*). The few labelled contacts exhibiting well defined junctional complexes (7.1% of grains counted; Table 1, Fig. 2*b*) were mostly asymmetrical and were generally established on dendritic spines. Labelled symmetrical junctions were rare

and found solely on dendritic shafts. Several dendritic profiles were labelled at different loci along the plasma membrane (Fig. 2*b*), suggesting that the receptors might be localized on the dendrites themselves rather than on the adjoining axons.

Axo-axonic appositions accounted for the second largest source of specifically labelled ^{125}I -FK binding sites (Table 1). Such appositions included either two axon terminals or one axon terminal and one or more axons. Although a streaming of synaptic vesicles towards the axonal interface was occasionally visible in one of the terminals involved, synaptic differentiations were never observed at the site of contact. One of the terminals, however, was often in synaptic contact with a dendritic profile, generally a dendritic spine (Fig. 2*c*). Previous studies have indicated that selective lesioning of nigrostriatal dopaminergic fibres results in a significant decrease in the number of opioid receptors in rat caudoputamen, suggesting that many of these receptors might be localized on dopamine terminals^{14–18}. The axo-axonic binding sites visualized in the present study may

Fig. 2 Electron microscopic autoradiographs from sections incubated with 1 nM ^{125}I -FK alone. The radioactivity is detected in the form of individual silver grains which were ascribed to underlying cellular constituents by means of 50% probability circles (see Table 1). In all cases illustrated here, the 50% probability circle encompasses two neuronal structures and the apposition of their respective plasma membranes. *a*, These two silver grains are associated with a non-junctional axo-dendritic interface involving a small axon terminal filled with numerous small clear synaptic vesicles. $\times 21,000$. *b*, The two silver grains on the left are associated with an asymmetrical axo-dendritic synaptic junction. A third silver grain on the right overlies the plasma membrane of the receiving dendrite. $\times 19,000$. *c*, This silver grain is localized at the interface of two axon terminals. Note the absence of synaptic specialization at the site of apposition. The synapse established on a dendritic spine by one of the terminals involved was not included within the resolution circle. $\times 26,000$. Development, D-19; exposure time, 10 weeks.

correspond to some of these postulated axonal receptors and could thus mediate, at least in part, the demonstrated effects of opioids on the striatal release of dopamine^{19,20}.

Finally, some of the labelled binding sites were associated with axo-somatic appositions (Table 1). Occasionally, a symmetrical synaptic differentiation was present at the site of contact between the axon terminal and the cytoplasmic membrane of the cell. Most of the nerve cells involved were of medium size (12–22 μm in diameter), with a large nucleus showing very little or no indentations and a small rim of surrounding cytoplasm containing very few organelles. These neurones were classified as spiny type 1 neurones, based on cytoarchitectonic analyses of rat neostriatum^{21,22}.

Taken together, the present results strongly suggest that ¹²⁵I-FK-labelled opioid receptors are primarily involved in the mediation or modulation of axo-dendritic, axo-axonic and, to a lesser extent, axo-somatic neural transmission in the rat neostriatum. The identity and site of release of the endogenous ligand(s) acting on these receptors remain to be determined. ¹²⁵I-FK labels both μ and δ opioid receptors^{23–25}, for which enkephalins have been proposed as natural endogenous ligands. Enkephalins could be released by terminals that either possess or are immediately adjacent to ¹²⁵I-FK binding sites, as suggested by the similarity, with respect to size, cytological features and synaptic relationships, between the terminals labelled in the present study and enkephalin-containing terminals previously identified in rat neostriatum by immunocytochemistry^{26,27}. Enkephalins could also be released at a distance from the labelled binding sites and diffuse in tissue to act on a relatively widespread population of receptors; this would account for the apparent lack of correlation between the distribution of enkephalin terminals and opioid receptors in rat striatum (see ref. 28). In any event, endogenous as well as exogenous opioids are likely to act primarily on non-differentiated membrane targets in rat caudate-putamen. Indeed, a major finding of the present study is that only a small proportion of the labelled binding sites was actually associated with synaptic junctions. This is in contrast to α -bungarotoxin^{29–31}, muscarinic³² and benzodiazepine³³ binding sites visualized by electron microscopy or horseradish peroxidase conjugation in rat central nervous system, for all of these have been found to be predominantly, although by no means exclusively, associated with synaptic contacts. That interneuronal communication can occur in the absence of membrane specialization has already been postulated for monoaminergic^{34,35} and peptidergic^{36–38} neurotransmission in the central and peripheral nervous systems. Correlative biochemical and immunohistochemical data³⁹ have indicated that opioids, in particular, may act non-synaptically in rat neostriatum, dorsal horn of the spinal cord and spinal trigeminal nerve. The non-junctional receptors visualized in the present study provide the first direct evidence for such a mode of action.

We thank Kathleen Leonard and Charles Hodge for technical assistance, Dr Michael Dennis for his help with the iodination of the peptide, Dr Barbara E. Jones for reviewing the manuscript, and Beverley Lindsay for typing it. The drug FK 33-824 was kindly provided by Dr Dietmar Roemer (Sandoz). This work was supported by a fellowship (E.H.), a scholarship (A.B.) and grant MA-7366 from the MRC of Canada.

Hybrid HLA-DC antigens provide molecular evidence for gene *trans*-complementation

Dominique J. Charron, Vincent Lotteau & Pascale Turmel

Laboratoire d'Immunogénétique, CHU Pitié Salpêtrière, 75013 Paris Cedex 13, France

In the mouse there are hybrid determinants for the immune region (*Ir*) of the genome which contribute to the diversity of class II (*Ia*) antigens of the major histocompatibility complex (MHC) and provide a molecular basis for *Ir* gene complementation^{1–4}. In man, two prominent families of Ia molecule, HLA-DR and HLA-DC (or DS)^{5,6}, have been identified which are respectively homologous to the murine I-E (E_α , E_β) and I-A (A_α , A_β) antigens⁷. Whereas DR antigens consist of a constant α -chain and an extremely polymorphic β -chain⁸, both the α and β subunits of DC antigens are structurally variable when different alleles are compared^{9,10}. The marked differences in the structure of the α - and β -chains of HLA-DC molecules result in electrophoretic variants which allow the haplotype of origin of each subunit to be identified by two-dimensional gel electrophoresis. We report here that gene *trans*-complementation occurs in cells heterozygous for the HLA-D region, resulting in the expression of hybrid HLA-DC molecules in addition to the parental forms. Generation of new HLA-D region hybrid molecules contributes to the qualitative diversity of human MHC class II antigens and has important functional implications in immune regulation.

HLA-DC molecules radiolabelled with ³⁵S-methionine were isolated by indirect immunoprecipitation from detergent-solubilized membranes of three cell lines—SC-CA (DR1 homozygous), GM 3163 (DR7 homozygous) and LES (DR1/DR7 heterozygous Epstein-Barr virus-transformed)—and a set of monoclonal antibodies previously reported to recognize HLA-DR and/or HLA-DC determinants was used to isolate and characterize the different HLA-DR and HLA-DC molecules present in the cell lines. Monoclonal antibody Genox 3.53 (ref. 11) recognizes the DC1 antigen¹² expressed on DR1-2- or W6-positive cells. As reported previously, the N-terminal amino acid sequence of the DC1 molecule isolated using this antibody is homologous to those of the murine I-A antigens for both the α - and β -chains^{5–13}. Immunoprecipitation of SC-CA

Fig. 1 Comparative IEF two-dimensional PAGE profiles of the DC α -chains from SC-CA (*DR1/DR1*), GM 3163 (*DR7/DR7*) and LES (*DR1/DR7*) cell lines. *a*, The DC1 α -chain isolated from SC-CA using the Genox 3.53 (anti-DC1) monoclonal antibody. 'A' indicates the position of actin (43,000 molecular weight). *b*, The DC1 α -chain from LES immunoprecipitated with Genox 3.53. *c*, The DC7 α -chain from GM 3163 DR⁻ immunoprecipitated with SG 171 or SG 520 is slightly higher and more basic. *d* Illustrates the ability of SG 171 to immunoprecipitate DC7 plus DC1 α -chains in LES DR⁻. The above pattern is identical to that obtained by mixing the DC1 α -chain from SC-CA and the DC7 α -chain from GM 3163 (panel *e*). *f*, Schematic representation of the DC1 α (○) and DC7 α (●) chains IEF20 PAGE patterns.

Methods: Cells were grown in RPMI 1640 supplemented with 10% fetal calf serum and labelled with ³⁵S-methionine in methionine-free medium as described in detail elsewhere¹⁵. The membranes were extracted with 0.5% Nonidet P-40 (NP40). The immunoprecipitated samples were separated by IEF two-dimensional PAGE. The ampholine mixture used in IEF consisted of pH 3.5 ampholine (0.5%) and pH 5-7 ampholine (1.5%). The second dimension was a 10% polyacrylamide slab gel. The panels show portions of autoradiographs of IEF two-dimensional PAGE of the immunoprecipitated proteins. The DC α -chains consist of four or five acidic spots.

(*DR1/DR1*) with Genox 3.53 enabled us to isolate the DC1 molecule; Genox 3.53 does not react with GM 3163. Two other monoclonal antibodies, SG 171 and SG 520, were used to characterize DC7 antigens. SG 171 was originally found to recognize I-A-like molecules from marmoset cell lines¹⁴. However, two-dimensional polyacrylamide gel electrophoresis (PAGE) and partial amino acid sequence data indicate that SG 171 displays an unusual pattern of reactivity for human Ia antigens. In addition to reacting with HLA-DR antigens of all the different alleles, including the *DR7* allele, SG 171 cross-reacts with the HLA-DC molecule present in *DR7* homozygous cells⁶. SG 171 is thus suitable for isolating the DC7 molecule after complete removal of the HLA-DR antigen. This was achieved through several cycles of immunoprecipitation with the monomorphic anti-HLA-DR monoclonal antibody, 1.41 (ref. 15). Antibody SG 520 has recently been reported to react only with DC7 molecules when used on cell lines that are *HLA-DR7* homozygous¹³. In the present work, the HLA-DC7 molecules were isolated by immunoprecipitation with SG 520 or SG 171 after depletion of HLA-DR. (We will refer to cell lysates from GM 3163 (*DR7/DR7*) and LES (*DR1/DR7*) depleted of HLA-DR antigen as GM 3163 DR⁻ and LES DR⁻, respectively.)

The immunoprecipitated HLA-DC antigen was analysed by two-dimensional PAGE as described previously. The use of non-equilibrium pH gradient electrophoresis in the first dimension provides a good separation of the β -chains of both

the HLA-DR⁸⁻¹⁵ and HLA-DC molecules⁶⁻¹⁴. However, the α -chains were poorly resolved by this procedure⁶⁻¹⁴, and we therefore used electrophoretic conditions known to maximize resolution of the acidic area of the gel. Analysis of the DC α -chain by isoelectrofocusing (IEF) two-dimensional PAGE in place of non-equilibrium pH gradient two-dimensional-PAGE revealed an acidic series of four or five discrete spots. This pattern is reproducible for a given DC α -chain. Furthermore, the α -chain species could be precisely located according to their position relative to the position of actin, a 43,000-molecular weight protein present in all MHC class II immunoprecipitates²⁻¹⁵. The DC1 α -chains isolated from SC-CA and LES cell lines using Genox 3.53 were indistinguishable by their IEF two-dimensional-PAGE profile (Fig. 1*a,b*). This complete identity was confirmed when a mixture of the two immunoprecipitates was analysed simultaneously on the same gel. Compared with the DC1 α -chain, the α -chain of the DC7 antigen isolated from GM 3163 as described above is slightly higher and more basic (Fig. 1*c*). The DC7 α -chain IEF two-dimensional-PAGE profiles were identical when GM 3163 was immunoprecipitated with antibody SG 520 or when another *DR7* homozygous cell line (Mann) was used. Structural polymorphism among *DC* α alleles has been reported previously using amino acid sequence data, DNA restriction fragment analysis and peptide mapping^{6,10,16}. Based on these results, we searched for electrophoretic variants of the DC α -chains. Because the IEF two-dimensional-PAGE patterns of DC α -chains are reproducible and distinguish between alleles, they can be used as molecular fingerprints to identify the haplotype of origin of the spots and therefore provide a method for typing the *DC* α locus.

Because IEF two-dimensional-PAGE analysis demonstrated haplotype specificity for the DC α -chains we used antibody SG 171 to investigate the DC antigens present in a cell lysate (LES DR⁻) from a *DR1/DR7* heterozygous individual carrying *DC7* on one chromosome and *DC1* on the other chromosome; this antibody would be expected to react only with the *DC7* species of DC molecule. However, the PAGE pattern of SG 171-reactive molecules isolated from LES DR⁻ cells revealed a more complex pattern than expected for the *DC7* α -chain (Fig. 1*d*); it represented the combined pattern of the DC1 and *DC7* α -chains. In fact, the pattern was identical to that obtained when DC1 and *DC7* antigen preparation were independently isolated from a *DR1* and a *DR7* homozygous cell respectively and co-electrophoresed on the same gel (Fig. 1*e*). We conclude from this that a monoclonal antibody possessing a biochemical specificity restricted to the *DC7* antigen is able to precipitate a DC1 α -chain associated with the *DC7* molecule in a *DR1/DR7* heterozygous cell line.

Several hypotheses were investigated to explain the presence of both α -chains. The DC1 α -chain could not carry a determinant recognized by SG 171 because the antibody would then be expected to immunoprecipitate DC1 from SC-CA (*DR1/DR1*), which it does not. This suggests that the DC1 α -chain is precipitated by SG 171 through its association with components of the *DC7* antigen. Because non-equilibrium pH two-dimensional PAGE reveals only one β -chain, corresponding to the *DC7* β -chain, our observation suggests that the *DC7* β -chain freely associates with both the *DC7* and DC1 α -chains. Furthermore, depletion of the *DR1/DR7* heterozygous cell lysate with antibody Genox 3.53 removes the complete DC1 molecule (DC1 α , DC1 β) but does not result in a decrease of the DC1 α -chain precipitated with SG 171, thus confirming the presence of an additional molecular species that is independent of the DC1 complex. Because the Ia antigen consists of two closely associated chains, an antibody to either chain would precipitate the α - β dimer. To investigate the possibility that the antibody reacted only with the *DC7* β -chain, isolated HLA-DC7 antigens from GM 3163 were precipitated, separated by SDS-PAGE in non-dissociating (unboiled) and dissociating conditions, electrophoretically transferred to nitrocellulose membranes and incubated with dilutions of antibody SG 171 and ¹²⁵I-protein A (Fig. 2). We found that antibody SG 171 bound strongly to the

Fig. 2 Detection of DC α -chain specificity of monoclonal antibody SG 171 by electrophoretic transfer of proteins from SDS-PAGE to nitrocellulose. Soluble membrane proteins from unlabelled GM 3163 cells were extracted at 10^8 cells ml^{-1} in 0.5% NP40 Tris-buffered saline (150 mM NaCl, 50 mM Tris, 0.02% NaN_3 , pH 7.0) for 15 min at 4°C. The insoluble material was removed by centrifugation at 100,000g for 60 min. The HLA-DR antigens were retained through eight cycles of immunoprecipitation with antibody 1.41, a monomorphic anti-HLA-DR and *Staphylococcus aureus* A protein¹⁵. The cell proteins depleted of DR reactivity were separated on a 10% polyacrylamide slab gel in non-dissociating conditions (no boiling) and dissociating conditions. Unlabelled polypeptides were transferred to a nitrocellulose membrane. After transfer, the filter was incubated with a 1:1,000 dilution of SG 171 and ^{125}I -protein A. DA 147 (ref. 17), an antibody directed against the α -chains (DR and DC), was used as control. DA 147 reacts with the complex (lane 2) and after dissociation only with the α -chain (lane 1). In contrast, SG 171 reacts with the complex (lane 4) and only with the DC β -chain (lane 3). Reactivity with the separated chains (α and β) in lanes 2 and 4 is the result of a low level of chain dissociation which occurs even without boiling the sample.

dimer and to only the β -chain when the complex was dissociated. An antibody directed against the α -chain (DA 147) was used as a control¹⁷.

From the above results, we conclude that in a heterozygous cell line, a DC β -chain can associate freely with the DC α -chain of either maternal or paternal origin, thus generating mixed-haplotype hybrid molecules. Four possible combinations could be generated by the different associations between the α - and β -chains of the DC loci and would therefore be expressed by individual cells. Several laboratories have presented serological evidence that in the mouse, certain Ia determinants exist as hybrid Ia molecules which are expressed on lymphocytes from F_1 animals but are not expressed on cells of either parental strain^{18,19}. Furthermore, combinatorial antigens can function effectively as in the mixed lymphocyte reaction and as restriction elements for T-cell recognition of antigen-specific clones^{1,20,21}. Jones *et al.*² and Silver²² have shown in biochemical studies that one gene product of the I-A region (A_β) and a gene product of the I-E region (E_α) could interact in either the *cis* or *trans* configuration in an F_1 animal. Similar associations occur between the A_α and A_β polypeptides in the appropriate F_1 , as demonstrated by Silver *et al.*³. No convincing serological or biochemical data for an HLA-D region hybrid antigen in humans are available. However, Hansen *et al.*²² observed HLA-D region *trans*-complementation in human T-cell clones that responded to tuberculin only when presented by accessory cells carrying both HLA-D region antigens possessed by the autologous cell donor²². Our finding that DC α - and DC β -chains from a heterozygous cell are capable of associating to form a novel molecule that may carry unique determinants present in the heterozygous cell and absent from both the maternal and parental haplotype may provide a molecular explanation for this. The latter data suggest the presence of new cell-surface molecules functioning as restriction elements independently of whether they originate from the maternal or paternal chromosome. Because the DR α -chains from different alleles are non-polymorphic, the haplotype of origin of the DR α -chain associ-

ated with a given DR β -chain should not be responsible for generating new Ia determinants. In contrast, the variability of the DC α -chain probably creates determinants of mixed haplotype. Such T-cell clones could represent the functional counterpart of the hybrid DC molecules described here.

Our results describe an additional source of structural diversity of the human Ia antigens which are expressed in HLA-D region heterozygous individuals and thus indicate that the number of potential Ia restriction sites is much greater than the number of Ia molecules encoded in the genome.

We thank F. Brodsky and P. Parham for the gift of Genox 3.53, J. Silver and S. Goyert for SG 171 and SG 520 and V. Van Heyningen and M. Steel for DA 147.

Tissue-specific transcription preference as a determinant of cell tropism and leukaemogenic potential of murine retroviruses

Daniel Celander & William A. Haseltine*

Dana-Farber Cancer Institute, Department of Pathology, Harvard Medical School, and * Department of Cancer Biology, Harvard School of Public Health, Boston, Massachusetts 02115, USA

Inoculation of susceptible strains of mice with the SL3-3 strain of murine leukaemia viruses induces T-cell lymphomas, whereas injection of the Akv strain does not¹⁻³. Recombinant viruses that contain the long terminal repeat (LTR) of the SL3-3 virus and the *gag*, *pol* and *env* genes of the Akv virus are also leukaemogenic⁴. The cell-type specificity of leukaemias induced by viruses containing different LTR sequences is due in part to the ability of the virus to replicate in the appropriate cellular environment⁴⁻⁷. One explanation of the role of the LTR in determination of both cell tropism and leukaemogenic potential is that the LTR encodes tissue-permissive transcriptional elements. We report here that there are differences in the transcriptional activity of the SL3-3 and Akv LTR sequences in different murine cell types, and that the sequences present in the LTR of SL3-3 exhibit significantly enhanced transcriptional activity in T cells compared with the corresponding region of the Akv LTR. The results suggest that transcriptional elements are primary determinants of cell tropism and of leukaemogenicity of these viruses.

To assess the ability of the Akv and SL3-3 LTR sequences to serve as promoter elements in different cellular environments, isogenic constructions⁸ were made in which the U3 regions of Akv (pAU3CAT) and SL3-3 (pSU3CAT) were placed 5' to the chloramphenicol acetyltransferase (CAT) gene⁹ (Fig. 1a). These

Fig. 1 Construction of plasmids used to assess promoter element function (a) and enhancer element activity (b) of murine LTR sequences. **a**, The plasmid subclones harbouring the 5'-LTR of Akv and SL3-3 (pLTR-A4 and pLTR-S3, respectively) were provided by J. Lenz⁴. The *Pst*I-*Ava*I fragment of the LTRs comprises the U3 and a small fraction of the R regions, extending from -443 to +31, relative to the viral RNA start site (designated as +1) for both viruses. This fragment was isolated from each LTR subclone where the natural *Ava*I site was converted to a *Hind*III site using *Hind*III synthetic linkers, and the natural *Pst*I site was converted to a blunt end. The plasmid that served as the recipient vector of the LTR fragments contains the entire CAT gene transcription unit⁹ (CAT coding sequences followed by the SV40 t-intron and polyadenylation signals) under the control of a SV40 early region promoter mutant that carries a deletion of nearly the entire 72-bp tandem repeat element (designated as pSVIXCAT, see below). The SV40 early region promoter, bounded by a synthetic *Xho*I site (5') and a natural *Hind*III site (3'), was removed from pSVIXCAT by successive digestion with *Xho*I, T4 DNA polymerase and *Hind*III enzymes in a fashion whereby the *Xho*I site was converted to a blunt end. The LTR fragments were ligated to the vector fragment containing the CAT gene transcription unit to generate plasmids in which the CAT gene is under the control of the transcriptional elements in the U3 region of Akv (pAU3CAT) or SL3-3 (pSU3CAT). The Akv and SL3-3 U3 regions are identical except for the presence of a single base insertion at nucleotide position 65 (designated by an asterisk) in SL3-3 relative to Akv, and the sequences within the repetitive elements (designated by arrows)⁴. The relative positions of CAAT, TATA and initiation (designated as +1) sequences are indicated. The location and boundary of LTR sequences used in pAU3CAT and pSU3CAT are shown relative to a typical retroviral LTR. **b**, To construct plasmids to assess enhancer element activity, a plasmid that carries the CAT gene under the control of the SV40 early region promoter (designated as pSV2CAT⁹) was digested with *Acl*I and *Sph*I to remove the majority of the 72-bp repeat region. The natural *Acl*I and *Sph*I sites were converted to *Xho*I sites using T4 DNA polymerase and a *Xho*I synthetic linker. Following digestion with *Xho*I and recircularization in the presence of DNA ligase, the resulting plasmid (pSVIXCAT) contains the CAT gene under the control of SV40 promoter sequences extending from -127 to +65 (relative to the 5'-most early start site)²⁹. The structure of this promoter deletion mutant is shown relative to the entire SV40 early region promoter found in pSV2CAT. The repetitive elements (designated by arrows), the origin of replication (ori), the TATA element (denoted as A/T) and early start site(s) (designated as +1) are illustrated. The SV40 promoter sequences present in pSVIXCAT are deficient in enhancer element activity; however, this activity can be restored by linkage of sequences containing enhancer activity to pSVIXCAT at a variety of sites relative to the SV40 early start site(s) (unpublished observations). For this study, a variant of SVIXCAT (designated as pSVIXCAT-AB3) was constructed in which the natural *Apa*I site⁴⁰ located greater than 2.1 kilobases from the SV40 early start site(s) was converted to a *Bgl*II site using T4 DNA polymerase and a synthetic *Bgl*II linker. The LTR subclones, pLTR-A4 and pLTR-S3, were digested with *Sau*3A and *Eco*RI, and a 620-bp *Sau*3A fragment containing 337 bp of U3 region sequences and 283 bp of *Sau*3A fragment D of pBR322 was isolated. The U3 region sequence present in the 620-bp *Sau*3A fragment consists of sequences extending from -443 to -106 (relative to the viral LTR start site in **a**), and contains the entire tandem repeat region of each virus. The 620-bp *Sau*3A fragment from each LTR subclone was inserted into pSVIXCAT-AB3 in either orientation at the unique *Bgl*II site. All manipulations were done according to standard recombinant DNA techniques⁸.

plasmids were introduced into cultured cells using either the calcium phosphate¹⁰ or the DEAE-dextran methods¹¹. After a transient expression period of 44–50 h, cell extracts were prepared, and the level of CAT enzymatic activity was measured⁹. Previous investigators have demonstrated that for constructions such as those used here, in which the sequences surrounding the RNA start sites are identical, and which differ only in sequences located remotely from the start site⁴, the level of indicator gene activity corresponds directly to the transcription rate^{12–15}. To determine the level of nonspecific and specific expression of the CAT gene in murine cells respectively, parallel transfection experiments were conducted in which cultured cells were exposed to plasmids containing either no eukaryotic promoter element (pSVOCAT)⁹ or the 3'-LTR of Rous sarcoma virus (pRSVCAT)¹⁶ located 5' to the CAT gene.

The level of CAT activity following transfection of these plasmids into murine fibroblast cells is shown in Fig. 2 and Table 1. In NIH 3T3 cells, the level of CAT gene expression of the plasmid containing the Akv LTR sequences is three times that of the plasmid containing the corresponding region of the SL3-3 virus. A similar result was obtained using mouse L cells, another murine fibroblast cell line. From these results, we conclude that in some murine fibroblasts the Akv LTR sequences are more potent than those of SL3-3 in promoting CAT gene expression.

A similar set of experiments was done using murine lymphoid cell lines. In marked contrast to the results observed using

fibroblasts, the level of CAT activity directed by the plasmid containing the SL3-3 LTR sequences was much greater than that directed by the plasmid containing the corresponding Akv sequences in all the T-cell lines tested (Table 1, Fig. 2b). The SL3-3/Akv ratio of transcriptional element activities was 0.3–0.6 in fibroblasts and 6–20 in T lymphocytes. The preferred expression in T-cell lines of the pSU3CAT plasmid relative to that of pAU3CAT is evidently not a consequence of virus infection because the SL3-3/Akv ratio of transcriptional element activity in SL3-3-infected L691 cells (designated as L691.SL3-3) is similar to that found in uninfected L691 cells. Preference for SL3-3 LTR sequences is also observed in primary cell preparations freshly eluted from the thymus of NFS/N mice (Table 1). Evidently, the transcriptional preference of SL3-3 LTR sequences in the established T-cell lines is a general property of T cells. The preferential expression of pSU3CAT is not observed on transfection of the murine B-cell line, M12 (Table 1), suggesting that preferential expression of pSU3CAT is not a general property of all lymphoid cells.

The only differences in LTR sequence between SL3-3 and Akv are located within the tandemly duplicated region located 221–443 base pairs (bp) from the RNA start site⁴, a region shown to include enhancer element functions of other murine retroviruses^{17–28}. This observation raises the possibility that sequences located far from the start site function as primary determinants of the efficiency of promoter element utilization in different cell types. To test this possibility, we measured the ability of the

Fig. 2 CAT activity directed by viral LTR sequences in different murine cells. Representative CAT assays for plasmids containing either the Akv U3 region, abbreviated AU3; the SL3-3 U3 region, abbreviated SU3; the 3'-LTR of Rous sarcoma virus, abbreviated RSV; or no eukaryotic promoter element, abbreviated SVO, linked 5' to the CAT gene transcription unit transfected in parallel into cultured cells are shown for NIH 3T3 fibroblasts (a) and AKSL3 T cells (b). c, Representative CAT assay of enhancer element function for plasmids containing either the SV40 promoter sequences lacking enhancer linked sequences, abbreviated SVIX-AB3; the Akv repeat region inserted at the *Bgl*II site 2 kilobases away from the SV40 early start site(s) in the same and opposite transcriptional sense as CAT gene transcription, abbreviated AE(+) and AE(-), respectively; the SL3-3 repeat region inserted at the *Bgl*II site and in the same and opposite transcriptional sense as CAT gene transcription, abbreviated SE(+) and SE(-), respectively; and the 3' LTR of Rous sarcoma virus, abbreviated RSV, linked to the CAT gene and transfected in parallel into cultured cells, is illustrated for AKSL3 T cells. Results are expressed as percentage conversion of ^{14} C-chloramphenicol to ^{14} C-chloramphenicol acetate by extracts containing 400 μ g protein in a and b and extracts containing 600 μ g protein in c. The insets show typical autoradiograms of CAT assays at 30 min (a), 80 min (b) and 30 min (c). The upper two spots correspond to the two isomers of ^{14} C-chloramphenicol monoacetate while the lower spot is the unreacted substrate, ^{14} C-chloramphenicol.

Methods: Each murine cell line was transfected with an equivalent amount of each plasmid DNA per transfection cocktail. The amount of DNA used for each experiment was within the linear range of optimal CAT activity (data not shown). The NIH 3T3 cell transfections were carried out as described previously¹⁰. The L cell and lymphoid cell transfections were done as described previously¹¹. After a transient expression period (44 h in promoter studies as in a and b; 50 h in enhancer studies as in c), the cells were washed with cold phosphate-buffered saline and resuspended in 200 μ l of 0.25 M Tris-HCl pH 7.9. Cell extracts were prepared by three cycles of freeze (-70°C)-thaw (37°C) treatment and centrifugation. *In vitro* CAT enzymatic assays were performed according to published procedures⁹ except that a final concentration of 2.4 mM acetyl coenzyme A was used in each extract assay. Analysis and quantitation of *in vitro* enzymatic assay was done according to previously described procedures⁹.

portion of the U3 region harbouring the tandemly repeated element of SL3-3 and Akv LTR sequences to function as transcriptional enhancer elements in murine T cells. The portion of the simian virus 40 (SV40) early region promoter that governs start site specificity^{29,30} was positioned 5' to the CAT gene (designated as pSVIXCAT-AB3), and the region harbouring the tandem repeat element of either SL3-3 or Akv was linked in *cis*, in both orientations, at a site about 2 kilobases from the SV40 early start sites (Fig. 1b). These plasmids were transfected into murine T cells (the AKSL3 cell line), and the levels of CAT activity were determined relative to pRSVCAT and pSVIXCAT-AB3 (Fig. 2c, Table 2). The level of CAT activity directed by the plasmid containing the SL3-3 repeat region was more than 30 times that of the pSVIXCAT-AB3 plasmid that lacks murine LTR sequences. In contrast to the marked increase in CAT activity observed for the plasmids containing the SL3-3 sequences, the level of CAT activity for those plasmids containing the Akv tandem repeat region sequences was increased only twofold relative to pSVIXCAT-AB3. Similar results were obtained using another murine T-cell line, the SL3B cell line (data not shown).

These experiments demonstrate that in T cells the region harbouring a tandemly repeated element of the SL3-3 LTR behaves as a transcriptional enhancer element^{31,32}; that is, it potentiates increased activity from a remotely located hetero-specific promoter element in an orientation-independent manner. Thus, the enhanced transcriptional activity of the SL3-3 LTR sequences relative to Akv sequences in murine T cells can be attributed to differences in enhancer element function encoded by sequences remotely located in the U3 region.

The increased rate of CAT gene transcription directed by the SL3-3 LTR element in T cells, relative to that of Akv sequences, permits a natural explanation of the T-cell tropism and leukaemogenic potential of the SL3-3 LTR-containing viruses. Replication of retroviruses proceeds via transcription from integrated proviruses. Tissue-specific differences in the rate of transcription of the magnitude observed here, 10–60-fold, may have a profound effect on the extent of viral replication, as such differences might be expected to be magnified as a power function on successive rounds of replication. Consonant with this

model, recent studies indicate that a correlation exists between the cell specificity of viral replication and the type of leukaemia induced by an isogenic set of viruses that differ only in the LTR regions^{3–7}. Thus, it is likely that viral replication, via transcription, in the appropriate cellular context may have a

Table 1 Relative activity of murine LTR sequences as promoter elements in various cell types

Cell type	Promoter element				SL3-3/Akv U3 region activity ratio
	None	RSV 3' LTR	Akv U3 region	SL3-3 U3 region	
Fibroblasts					
NIH 3T3	0.02	1.00	4.94	1.52	0.31
L	0.05	1.00	5.96	3.74	0.62
Lymphoid cells*					
AKSL3	0.01	1.00	0.76	4.50	5.94
SL3B	0.01	1.00	0.51	10.46	20.51
L691	0.04	1.00	0.64	4.09	6.39
L691.SL3-3	0.01	1.00	0.24	1.73	7.20
NFS/N thymocytes	0.85	1.00	0.92	13.57	14.75
M12	0.01	1.00	2.76	1.75	0.64

The CAT activity of each plasmid is normalized relative to the absolute activity of the 3'-LTR of RSV in pRSVCAT within each cell line. Absolute activity for each plasmid in every cell line was calculated from the slope of the line in the initial velocity of CAT enzymatic assay for cell extracts containing 400 μ g of protein as depicted in Fig. 2. The absolute activity in any given cell line transfected with each plasmid is expressed in terms of % conversion per h in the *in vitro* assays, and may be obtained quantitatively by multiplying the relative value in the table by the absolute activity value of the same cell line transfected with pRSVCAT. The absolute activity of pRSVCAT in each cell line is given in parentheses: NIH 3T3 ($2.06\% \text{ h}^{-1}$), L ($0.64\% \text{ h}^{-1}$), M12 ($2.5\% \text{ h}^{-1}$), AKSL3 ($4.87\% \text{ h}^{-1}$), SL3B ($2.04\% \text{ h}^{-1}$), L691 ($0.84\% \text{ h}^{-1}$), L691.SL3-3 ($2.37\% \text{ h}^{-1}$) and NFS/N thymocytes ($0.03\% \text{ h}^{-1}$). Results shown here reflect an average of at least two independent transfection experiments, and CAT assays performed using extracts containing 400 μ g of protein. The range of activities around a particular value varied by not more than 30% of that value.

* Several T-cell lines established from murine T lymphomas were used as recipients and include: AKSL3, a cell line established from a spontaneous tumour of an AKR mouse (the cell line from which the SL3-3 virus was isolated)³⁶; SL3B, a cell line derived from a thymic T-cell tumour of an AKR mouse that had been injected with the SL3 virus³⁷; the uninfected murine T-cell line, L691 (ref. 38); L691.SL3-3, L691 cells infected *in vitro* with SL3-3 virus; and freshly eluted primary thymus cells isolated from NFS/N mice³⁹. The murine B-cell line, M12, was also used as a recipient.

Table 2 Relative activity of murine LTR sequences as enhancer elements in the murine T-cell line AKSL3

Promoter element	Viral repeat region and orientation	Relative activity	Relative-fold enhancement
RSV 3'-LTR		1.000	—
SV40 early region mutant	None	0.01	1.00
SV40 early region mutant	Akv, sense	0.01	1.00
SV40 early region mutant	Akv, antisense	0.02	2.00
SV40 early region mutant	SL3-3, sense	0.37	37.00
SV40 early region mutant	SL3-3, antisense	0.34	34.00

The CAT activity of each plasmid is normalized relative to the absolute activity of the 3'-LTR in pRSVcat within the T-cell line AKSL3. Absolute activity was determined as described in Table 1. Results shown here are an average of three transfection experiments and CAT assays were performed using extracts containing 600 µg of protein. The range of activities around a particular value varies by not more than 30% of that value. Fold-enhancement for plasmids containing viral repeat regions was determined relative to pSVXCAT-AB3, the plasmid lacking a viral repeat region.

major role in the induction of a tissue-specific disease by these viruses. Finally, recent studies suggest that murine leukaemia viruses may induce disease by proviral integration adjacent to common loci^{28,33-35}, some of which harbour known oncogenes^{28,34}. Analysis of these integration sites indicates that these loci may be transcriptionally activated by the adjacent viral LTR enhancer element^{28,33-35}. We speculate that an additional, if not simultaneous, characteristic of the LTR of a T-cell leukaemogenic virus is to provide strong enhancer element function sufficient to transcriptionally activate adjacent cellular loci.

We thank Corri Gorman and Bruce Howard for gifts of plasmids, Ester Hays for gifts of AKR T-cell lines, Philip Leder for the M12 cell line, and Jack Lenz, Joseph Sodroski, Craig Rosen and Miles Cloyd for helpful discussions. We thank Ms Donna Artz for help in preparation of this manuscript. This work was supported by NCI grant CA19341.

The blood/brain barrier prevents the passive diffusion of proteins and metabolites from cerebral blood vessels into tissue spaces around neuronal and glial cells. To provide nutrients for these cells, transport mechanisms must exist and indeed have been demonstrated for metabolites¹. We now show that monoclonal antibodies against rat and human transferrin receptors label blood capillaries in the brain but not in other tissues. In the rat this labelling occurs after injection of antibody into the blood, thus the receptors seem to be accessible at the endothelial surface. It is possible that transferrin receptors are expressed on these cells to allow transport of transferrin (and thus iron) into brain tissues.

The MRC OX-26 mouse IgG2a monoclonal antibody is specific for transferrin receptors on the basis that it binds to a detergent-solubilized molecule that can bind ¹²⁵I-transferrin and precipitates a dimer of glycoproteins of apparent molecular weight ~95,000 (ref. 2). Cryostat sections were cut from various rat tissues and stained with MRC OX-26 antibody, followed by peroxidase-conjugated rabbit F(ab')₂ anti-mouse IgG antibody³. One notable reaction occurred with what appeared to be capillaries in the brain; this is shown in Fig. 1a for a 5-µm section from the cerebellum of rat brain and in Fig. 1b for a 30-µm section. The thicker section clearly shows the branched structures, and similar patterns were seen in sections from the brain cortex and spinal cord. Sections from other rat tissues including thymus, lymph node, spleen, heart, kidney, liver, pancreas and small intestine were also stained with OX-26 antibody² but labelling of capillaries was not observed in these sections. In the sections of brain tissue, scattered cells having the morphology of neurones were also stained (for example, see Fig. 1a).

To test whether the antigen recognized by the MRC OX-26 antibody was accessible at the endothelial surface, 2.5 mg of MRC OX-26 IgG was injected intravenously (i.v.) into 4-week-old PVG/c rats and control animals were injected with an equal amount of W6/32 antibody (an IgG2a specific for human histocompatibility locus antigen) or normal mouse IgG. The rats were killed 20 min or 16 h after antibody injection and cryostat sections were cut from their brains and stained with peroxidase-conjugated rabbit anti-mouse IgG antibody. Figure 1c shows clear labelling of the capillaries in a section from an animal given OX-26 antibody 20 min previously, but not in a section from an animal injected with control antibodies. Labelling was still evident 16 h after the injection of antibody, but was weaker than at the earlier time (not shown).

The above results suggest that transferrin receptors are expressed at the luminal surface of the endothelium of rat brain capillaries. Alternatively, the staining could be due to a spurious cross-reaction with an unrelated molecule; this possibility would be excluded if similar reactions were seen with other monoclonal antibodies against transferrin receptors. Several antibodies that react with human transferrin receptors have been described and the antibodies B3/25 (ref. 4), T56/14 (ref. 5) and OKT9 (ref. 6) unequivocally have this specificity. When used to stain sections from two human brains, these antibodies stained the capillaries in both cases. In one case, sections from somatic and

Fig. 1 Staining of sections from rat and human brain with anti-transferrin receptor monoclonal antibodies. *a, b*, Labelling by peroxidase immunohistochemistry of 5- μ m and 30- μ m cryostat sections cut from the cerebellum of 12-week-old PVG/c rats. The sections were cut, fixed and stained with MRC OX-26 monoclonal antibody, followed by peroxidase-conjugated rabbit F(ab')₂ anti-mouse IgG antibody exactly as described in ref. 3. The monoclonal antibody was used as a tissue culture supernatant from OX-26 hybridoma cells. The control shown at the right of each section comprised an adjacent section stained with an antibody that did not react with rat tissues (IgG1 or IgG2a control antibodies were equally unreactive). The arrow in *a* indicates a labelled neurone. *c, d*, A 25- μ m section from the cerebral cortex of a rat which had been given 2.5 mg of OX-26 IgG i.v. 20 min before killing. This section was stained with peroxidase-conjugated rabbit F(ab')₂ anti-mouse IgG antibody without any first incubation with monoclonal antibody. The control is a section from a rat given 2.5 mg of W6/32 antibody (in ascites fluid) 20 min before killing. *d*, A 9- μ m cryostat section from the cerebellum of a 25-yr-old female human; the tissue was obtained during autopsy (~7 h after death). The section was stained with B3/25 monoclonal antibody and the bound antibody detected by alkaline phosphatase immunohistochemistry, in which the enzyme was cross-linked to the monoclonal antibody by a bridge of rabbit anti-mouse IgG antibody and mouse monoclonal anti-alkaline phosphatase antibody⁹. The sections in *a* and *d* are at a magnification 2.5 times greater than that of *b* and *c*, and the bars in the control sections represent 50 μ m.

visual cortex, basal ganglia, cerebellum, mid-brain and spinal cord were stained and labelling of capillaries was evident in all these areas. Figure 1*d* shows a typical result for antibody B3/25 staining a section of cerebellum. In addition, staining for factor VIII, an established marker for capillaries⁷, was done using the F8.44.20 monoclonal antibody⁸ and the patterns of reaction (not shown) were indistinguishable from those in Fig. 1*d*. In other human tissues, the capillaries were clearly labelled with the anti-factor VIII antibody, but staining of capillaries was not observed with the anti-transferrin receptor antibodies⁵. Labelling of human neurones is not evident in Fig. 1*d*, but scattered neuronal staining was seen in sections of human as well as in rat brain.

The reaction of blood capillaries in human and rat brain with four different monoclonal antibodies suggests strongly that transferrin receptors are expressed on the capillaries, and the results in rat show that these are located at the luminal surface. It is possible that these molecules are involved in the transport of transferrin across the blood/brain barrier.

We thank Margaret Hughes for technical assistance, Stan Buckingham for photography, Dr T. Powell for advice on obtaining rat brain material, Dr A. N. Barclay for peroxidase-conjugated rabbit F(ab')₂ anti-mouse IgG antibody and Dr I. S. Trowbridge for antibodies B3/25 and T56/14. This work was supported in part by the Leukemia Research Fund and the Wellcome Trust. W.A.J. is an Exhibition of 1851 Scholar and acknowledges a BCHCRF traineeship award.

Rabies is one of the oldest diseases known to man, but its successful control has remained elusive. Although effective vaccines of tissue culture origin against rabies do exist¹, such preparations are expensive. Live vaccinia virus (VV) recombinants expressing influenza or hepatitis B antigens have recently been used to immunize against these diseases²⁻⁴. We have now used this approach to produce a novel rabies vaccine. We first altered the rabies glycoprotein cDNA⁵ by site-directed mutagenesis and removed the poly(dG) tail. We then aligned the modified cDNA with an early VV promoter sequence inserted within a cloned copy of the vaccinia thymidine kinase gene and transfected this plasmid into VV-infected cells. Recombination between the virus and the plasmid resulted in a recombinant virus harbouring the rabies glycoprotein cDNA. Inoculation of rabbits with the live recombinant virus induced high titres of rabies virus-neutralizing antibodies, and scarification with the recombinant VV protected mice against challenge with street rabies virus.

The rabies virus contains five virus-encoded proteins, only one of which, the glycoprotein, traverses the lipid bilayer envelope. The glycoprotein spike is thus the sole viral component capable of reacting with virus-neutralizing antibodies and eliciting their production. The full-length coding sequence of the ERA strain rabies glycoprotein messenger RNA has been isolated⁵ and its sequence expressed in a bacterial host⁶. Parallel experiments have been described⁷ using the related CVS strain of rabies, but no protection against rabies using the bacterially synthesized material has yet been reported. These data suggest that post-translational modification and/or presentation of the glycoprotein may be important parameters in the use of this antigen in protection against rabies. We have explored the use

§ Present address: AFRC Animal Breeding Research Organisation, King's Buildings, West Mains Road, Edinburgh EH9 3JQ, UK.

Fig. 1 Restructuring of the rabies glycoprotein cDNA. *a*, The cDNA segment between the *Bgl*II/*Pst*I site at one extremity and a downstream *Mst*II site is replaced by a synthetic double-stranded oligonucleotide adaptor to delete the upstream poly(G)/poly(C) sequence. In *b* the codon for amino acid 8 in the cDNA sequence is changed from CTA to CCA using oligonucleotide-directed mutagenesis. Amino acids of the primary translation are numbered; numbers in parentheses give the amino acid positions in the mature glycoprotein molecule after removal of the N-terminal signal sequence. The precise cleavage sites for *Mst*II and *Bgl*II, respectively, are indicated by 'm' and 'n'. Asterisks indicate mismatches and the *dam* methylation sequence.

Methods: Restructuring the initiation region: In plasmid ptg150(1), the rabies glycoprotein cDNA of Anilionis *et al.*⁵ was introduced, using octameric *Pst*I-*Bgl*II oligonucleotide adaptors¹⁶, into a unique *Bgl*II site inserted at the *Hind*III site of plasmid pBR327 (R.L., unpublished data). This plasmid was digested partially with *Bgl*II and completely with *Mst*II, and the appropriate linear fragment isolated by electrophoresis on a low gelling temperature agarose gel. Oligonucleotides 5'-dGATCTAATATGGTTCC-3' and 5'-dTGAGGAACCATATTA-3' were synthesized using a previously described technique¹⁷. These were hybridized together and ligated between the *Bgl*II and *Mst*II extremities of the purified linear plasmid, permitting recircularization and generating plasmid ptg155(2). Correction of triplet 8: The oligonucleotide 5'-dTACACGATCCCAGACAAGC-3' for localized mutagenesis¹⁸ contains two mismatches with the original sequence: a T to C transition correcting the leucine triplet, CTA, to proline, CCA, and an adjacent A to C transversion in the sequence GATA. This generates a *dam* methylation sequence GATC which favours incorporation of the oligonucleotide sequence by selective mismatch correction *in vivo* following primed repair and transfection (see refs 19, 20 for theoretical background to this strategy). The *dam* methylation sequence is itself a restriction recognition site for the enzyme *Sau*3A and permitted rapid identification of correct constructs from digestion profiles of replicative form DNAs. Fragment exchange generated the final reconstructed plasmid ptg155-PRO. Note that the *Eco*RI/*Hind*III fragment was cloned in the reverse orientation of that presented here: the lower strand (complementary to the oligonucleotide) was present in the parental single-stranded M13 bacteriophage recombinant. Hybrid plasmid assembly: Miniplasmid ptg1H was constructed starting from plasmid pML2²¹ (a spontaneous deletion derivative of vector plasmid pBR322 lacking the segment between nucleotides 1,098 and 2,490: probable sequence at deletion boundaries AGCTTCACGGCCAGC, R.L., unpublished results). The *Pst*I recognition sequence was removed by inserting a 692 base pair (bp) *Aha*III-*Aha*III fragment of pUC8²² between two *Aha*III sites of pML2 (removing 19 bp) and the linker-tailing method²³ was used to insert a *Hind*III linker between the *Nru*I and *S*₁-treated *Eco*RI sites of this plasmid (ptg1H). The 4.6 kb *Hin*-J fragment of VV DNA bearing the *tk* gene¹¹ was inserted at the unique *Hind*III site to generate ptg1H-TK. The VV *Sal*-S fragment, carrying the 7.5K promoter²⁴, was isolated in an M13 vector²⁵ as a (shotgun) *Sal*I clone of VV DNA (M13tg*Sal*-S). Here a *Sca*I site lies 33 nucleotides downstream of the transcription start point and 18 nucleotides upstream from the putative initiation codon for the 7.5K gene²⁴. This clone was truncated using the linker-tailing protocol²³ to insert a *Bgl*II linker oligonucleotide 5'-dCAGATCTG-3' between the *Sca*I site and the M13 vector *Bam*HI site after filling the extremity generated by *Bam*HI digestion by DNA polymerase (Klenow fragment) treatment. This eliminates both the *Sca*I site and the downstream *Sal*I (*Acc*I) site, the upstream site becoming unique (M13tg7.5K). The promoter fragment (~270 bp) was excised with *Acc*I and *Eco*RI and ligated between the unique *Cl*A and *Eco*RI sites (see ref. 26) within the *tk* gene present in ptg1H-TK and generating ptg1H-TK-7.5K, deleting 33 bp (see ref. 27 for an alternative cloning strategy). The *Bgl*II-*Bgl*II fragment from ptg155-PRO was subsequently inserted into the unique *Bam*HI site of ptg1H-TK-P7.5K to generate pVVTGgRAB.

of a VV vector to express the rabies glycoprotein coding sequence.

Expression of exogenous protein coding sequences in VV involves two steps. First, the exogenous coding sequence is aligned with a functional VV promoter and inserted *in vitro* at a site within a (non-essential) segment of VV DNA cloned into a suitable bacterial plasmid replicon. Second, the flanking VV sequences now permit homologous recombination *in vivo* between the plasmid and the viral genome. Double reciprocal recombination results in transfer of the DNA insert from the plasmid to the viral genome, wherein it is propagated and expressed^{2,4,8,9}.

The ERA rabies glycoprotein coding sequence⁵ carries two impediments to its successful translation and expression as an antigen. First, the ATG corresponding to the initiation codon of the mature message lies adjacent to a poly(dG) sequence introduced by the cDNA cloning procedure. This was eliminated by replacing the appropriate cDNA segment by a synthetic double-stranded adaptor, deleting the G/C tail and reconstructing the initiation codon region (plasmid ptg155; Figs 1a, 2). Second, the eighth amino acid of the mature glycoprotein (lacking its signal sequence) of rabies virus ERA and CVS strains is proline^{7,10}, whereas in the cDNA isolated by Anilionis *et al.*⁵, the triplet at this position codes for leucine. The appropriate segment of glycoprotein cDNA was subcloned into a single-stranded bacteriophage vector and oligonucleotide-directed mutagenesis was used to correct the triplet CTA (Leu) to CCA (Pro) (Fig. 1b).

A *Hind*III fragment (*Hin*-J) of the VV genome containing a complete thymidine kinase (*tk*) gene has been used previously to permit recombinational exchange of inserted DNA into the VV genome^{2,3,9}. Transfer of an insert in the *tk* gene to the VV genome creates an easily recognized TK-deficient (TK⁻) virus (Fig. 1). Next, a VV promoter was required to drive the expression of the inserted rabies glycoprotein coding sequence. The promoter of the early VV gene encoding a 7,500 molecular weight (MW, 7.5K) protein has previously been used successfully for a similar purpose^{2,3}, and we inserted this segment into the cloned *tk* gene (Fig. 1 legend). The corrected rabies glycoprotein cDNA was introduced downstream of the (7.5 K) promoter to generate pVVTGgRAB (Fig. 1 legend). This plasmid carries all the elements necessary for transfer of the rabies glycoprotein coding sequence to the VV genome and its subsequent expression.

The strategy devised by Smith *et al.*² relies on *in vivo* exchange between a plasmid bearing an insert within the VV *tk* gene and wild-type viral genome to inactivate the virus-borne *tk* gene. TK⁻ viruses may be selected by plating on a TK⁻ cell line in the presence of 5-bromodeoxyuridine (BrdUrd)⁹. TK phosphorylates BrdUrd to the 5'-monophosphate, which is converted subsequently to the triphosphate. This compound is an analogue of dTTP; its incorporation into DNA prevents correct development of the virus. A TK⁻ virus can, however, replicate its DNA normally and give rise to visible viral plaques on a monolayer of an appropriate TK⁻ cell line.

VV propagates in the cytoplasm of infected cells rather than

Fig. 2 Immunoprecipitation of proteins synthesized after infection by the VV-rabies recombinant. *a*, Polyclonal antiserum R215 (Wistar) raised against the purified glycoprotein was used; *b*, *c*, identical results were obtained with two monoclonal virus-neutralizing antibodies (509-6 (*b*) and 101-1 (*c*); Wistar) which identify different epitopes on the rabies glycoprotein. The cell monolayers were infected with: 1, recombinant VVTGgRAB-26D3; 2, wild-type VV; 3, no virus. Numbers on the left-hand side represent molecular weight standards ($\times 10^{-3}$).

Methods: Semi-confluent monolayers of LTK⁻ cells ($\sim 10^6$ per plate) were adsorbed with VVTGgRAB-26D3 (50 PFU per cell) for 1 h at room temperature, methionine-free culture medium was added and after 30 min each plate was supplemented with 50 μ Ci of ^{35} S-L-methionine (1,265 Ci mmol⁻¹; Amersham) and incubation continued at 37 °C for 4 h. Cells were collected and resuspended into immunoprecipitation buffer containing protease inhibitors. After sonication and clarification, proteins bound by anti-rabies antisera were recovered by affinity chromatography on protein-A-Sepharose and displayed by gel electrophoresis and fluorography by a modification of a previously described protocol²⁸.

in the nucleus. It is thus unable to take advantage of the host DNA replication and transcription machineries and instead carries in the virion those components necessary for the onset of viral gene expression. For the purpose of generating recombinants, it is necessary simultaneously to infect cells with live VV and introduce the cloned DNA segment of interest by calcium-mediated transfection. However, because the generation of recombinants is limited to those few cells competent for DNA transfection, we used an indirect 'congruence' strategy to reduce the background of non-recombinant parental viruses. This was achieved by using as live infecting virus a ts (temperature-sensitive) mutant of vaccinia unable to propagate at the non-permissive temperature¹¹. When cells infected with a ts mutant in non-permissive conditions are transfected with wild-type virus DNA, viral multiplication occurs only in those cells competent for transfection.

Monolayers of primary chick embryo fibroblast (CEF) cells were infected with VV-Copenhagen ts26 (0.1 plaque-forming units, PFU, per cell), incubated at the permissive temperature (33 °C) for 2 h, then transfected with a calcium phosphate coprecipitate of VV-Copenhagen wild-type DNA ($\sim 0.5 \mu$ g per 10^6 cells) and the recombinant plasmid pVVTGgRAB (3.0 μ g per 10^6 cells). After incubation for 2 h at the non-permissive temperature (39.5 °C), the cells were rinsed and incubated for 48 h at 39.5 °C. Dilutions of ts⁺ virus emerging were reinfected onto a monolayer of mouse LTK⁻ cells at 37 °C and incubated in the presence of BrdUrd (100 μ g ml⁻¹). TK⁻ plaques were obtained from cells that had received the recombinant plasmid, whereas in control cultures without the plasmid no plaques were visible (data not shown).

Table 1 The potential of the recombinant virus to induce rabies-neutralizing antibodies

Post-vaccination day	VVTGgRAB-26D3	Vaccinia wild-type
0	<10	<10
11	10,000	<10
14	>30,000	<10

Rabbits were injected intradermally with 2×10^8 PFU of VVTGgRAB-26D3 virus or with wild-type VV. Inoculations were made in three points on the back. On days 0, 11 and 14, rabbits were bled and sera tested for the presence of rabies virus-neutralizing antibody by a modified rapid fluorescent focus inhibition test¹⁵. Rabies virus was preincubated for 1 h with dilutions of the rabbit antisera and adsorbed to BHK-21 cells. Productively-infected cells were stained after 24 h using a direct immunofluorescence technique. Titres given as the highest dilution at which 50% inhibition of virus infection was observed.

Correct double reciprocal recombination between the hybrid vaccinia-rabies plasmid and the VV genome exchanges the viral *tk* gene for the insert-bearing *tk* gene present on the plasmid. We confirmed the presence of the rabies glycoprotein cDNA by digesting DNA purified from TK⁻ virus with *Hind*III. The 4.6 kilobase (kb) *Hin*-J fragment was absent from these viruses, as we expected, and two new fragments of ~ 1.1 and 5.5 kb revealed the presence of an insert containing an internal *Hind*III site. Southern blotting confirmed that the insert hybridized with rabies glycoprotein cDNA (data not shown) and one recombinant, VVTGgRAB-26D3, was retained. This virus was assessed for its ability to direct the synthesis of rabies glycoprotein in tissue culture cells.

First, monolayers of LTK⁻ cells infected with VVTGgRAB-26D3 were examined for *in situ* immunofluorescence using virus-neutralizing antibodies. Most cells exhibited strong fluorescence associated with the cytoplasmic membrane, whereas non-infected cells and cells infected with the non-recombinant virus showed no fluorescence (data not shown). We infected monolayers of semi-confluent LTK⁻ cells with VVTGgRAB-26D3; polyclonal rabies antiserum as well as two different virus-neutralizing monoclonal antibodies precipitated a protein migrating as a diffuse band of MW 66,000 (Fig. 2). This molecular weight corresponds to the size of ERA virus glycoprotein¹². Furthermore, sera from rabbits immunized with VVTGgRAB-26D3 recognized and bound radiolabelled authentic viral glycoprotein (data not shown). Sera from animals immunized with the non-recombinant VV gave no such reaction. We subsequently examined the potential of the recombinant virus to induce rabies-neutralizing antibodies. Even at the highest dilution of the 14-day antisera, complete neutralization of the virus was achieved.

These results demonstrate that the recombinant VVTGgRAB-26D3 not only induces the production of antibodies reacting with rabies virus, but also that antisera from immunized animals are capable of inactivating rabies virus *in vitro*. This encouraged direct protection testing. Mice immunized by intradermal inoculation of VVTGgRAB-26D3 virus resisted challenge with large

Table 2 Resistance of immunized mice to rabies virus

Immunizing agent	% Protection
None	0
Vaccinia wild-type virus	0
Recombinant virus VVTGgRAB-26D3	100

Female mice (ICR strain) were infected intradermally by scarification with $\sim 5 \times 10^7$ PFU of VVTGgRAB-26D3 or wild-type VV. Four skin scratches were made on the base of the tail using a hypodermic needle and virus suspension rubbed over the abrasion. On day 15 all vaccinated and control animals were infected by intracerebral inoculation with CDC strain tissue-culture adapted street virus (2,400 mouse LD₅₀ units). Test animals were monitored for 2 months post-challenge: unprotected mice succumbed after 8–10 days.

Fig. 3 Comparative binding of VVTGgRAB and ERA virus antigens with a panel of monoclonal antibodies. Solid bars, ERA virus; cross-hatched bars, VVTGgRAB virus.

Methods: Antigens (100 ng) were dried on microtitre plates and treated for 30 min with phosphate-buffered saline (PBS) containing 10% γ -globulin-free horse serum (Gibco). After draining, monoclonal antibody (1:1,000 dilution of ascites fluid; 25 μ l) was added, incubated for 1 h at 37 °C and washed with PBS. Each well then received 25 μ l of ^{125} I-labelled goat anti-mouse antibodies (30,000 c.p.m., specific activity, 0.5 mCi mg $^{-1}$). After further incubation (37 °C, 1 h) and washing with PBS, the bottom of each well was cut out and radioactivity determined.

doses of street rabies virus, whereas mice similarly immunized with wild-type VV alone were not protected (Table 2).

To assess the authenticity of the recombinant rabies glycoprotein, reactivity with a panel of monoclonal antibodies directed against rabies glycoprotein and other viral proteins (N, NS and M) was examined. The binding activity of the recombinant glycoprotein with 44 anti-glycoprotein monoclonal antibodies was almost identical to that observed with purified ERA rabies virus, whereas only the ERA virus reacted with anti-N, -NS and -M antibodies (Fig. 3). This demonstrates that the rabies glycoprotein produced by VVTGgRAB virus-infected cells is qualitatively indistinguishable from the native glycoprotein of ERA virus.

Vaccinia virus has been used extensively as a live vaccine to control and eradicate smallpox (see ref. 13 for review); it has been developed as a cloning and expression vehicle for hepatitis B, influenza and herpes antigens and protection has been achieved by vaccination with appropriate influenza- and herpes-VV recombinants^{2-4,14}. We demonstrate here that live VV expressing the rabies glycoprotein is capable of conferring protection against experimental rabies infection. Attenuated viruses such as VV are particularly appropriate vehicles for vaccine production: their preparation and administration can avoid costly procedures involving propagation of the pathogenic agent on cultured mammalian cells and subsequent toxicity testing.

We thank A. Kirn and D. Nayak for helpful discussions and P. Chambon, E. Eisenmann and P. Kourilsky for encouragement and critical reading of the manuscript, A. Balland for preparing the synthetic oligonucleotides used in this work, D. Villeval and F. Jaeger for verifying constructs by sequencing and E. Chambon and F. Daul for assistance in preparing this manuscript. This study was supported in part by NIAID grant AI-09706.

Molecular cloning and characterization of the HTLV-III virus associated with AIDS

Beatrice H. Hahn, George M. Shaw, Suresh K. Arya, Mikulas Popovic, Robert C. Gallo & Flossie Wong-Staal

Laboratory of Tumor Cell Biology, Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

We recently reported the isolation and characterization of a novel human T-lymphotropic retrovirus, HTLV-III, in patients with acquired immune deficiency syndrome (AIDS) and in those at risk for the disease¹⁻⁴. After extensive sero-epidemiological studies^{3,5,6}, together with numerous virus isolations from these patients^{1,7}, we concluded that HTLV-III is the causative agent of AIDS. Here we report the molecular cloning and characterization of two highly related but distinct forms of the HTLV-III genome. The viral genome is ~10 kilobases long and is detected in HTLV-III-infected cells but not in uninfected cells, including normal human tissue,

indicating that this virus is exogenous to man. We also demonstrate distant nucleic acid sequence homology between the cloned genome of HTLV-III and those of HTLV-I and HTLV-II. The availability of the cloned HTLV-III genome will now allow an unambiguous comparison of this virus with other retroviruses that also have been associated with the pathogenesis of AIDS⁸⁻¹¹, and moreover, will facilitate the development of diagnostic and therapeutic measures in the treatment of AIDS.

All human retroviruses that have been extensively characterized are lymphotropic, especially OKT4 lymphotropic, and induce formation of multinucleated cells on infection. These viruses also contain a relatively high-molecular weight reverse transcriptase with preference for Mg^{2+} and possess a major core protein of relative molecular mass 23,000–25,000. We named the viruses human T-cell leukaemia viruses, or HTLV, in accordance with recent convention^{12,13}. The first two subgroups of HTLV (I and II) are associated with T-cell malignancies and can transform T cells *in vitro*¹². HTLV-III has many properties in common with HTLV-I and HTLV-II but has cytopathic rather than transforming activity. The crucial step allowing us to isolate and characterize HTLV-III, and to produce sufficient purified viral reagents for serological assays, was the successful transmission of HTLV-III to an immortalized human T-cell line (HT) and to clones derived from this line which were significantly resistant to the cytopathic effects of the virus. This led to the establishment of permanently infected, high-producer cell lines for continuous production of HTLV-III². One of these cell lines, H9/HTLV-III, produces large quantities of HTLV-III and serves as the principal producer cell line for immunological assays used to detect virus-specific antigens and antibodies in sera from AIDS patients. The uninfected parental cell line (HT) and its derivatives (H9 and H4) were negative by all criteria for retrovirus infection, including HTLV-I, HTLV-II and HTLV-III (M.P., in preparation). To clone the HTLV-III genome, we isolated unintegrated viral DNA after acute infection of H9 cells with concentrated HTLV-III and cloned this DNA into a λ phage library to be screened with viral cDNA.

Concentrated virus from the H9/HTLV-III cell line was used to infect fresh uninfected H9 cells at a multiplicity of 50 viral particles per cell and cultures were collected after 4, 10, 15, 24 and 48 h. Extrachromosomal DNA was extracted according to the procedure of Hirt¹⁴ and assayed for its content of unintegrated viral DNA using HTLV-III cDNA as a probe. The synthesis of this cDNA was primed with oligo(dT) and reverse-transcribed from poly(A)-containing RNA of virions that had been banded twice on sucrose density gradients¹⁵. Unintegrated linear viral DNA was first detected after 10 h and was also present at the subsequent time points. Figure 1 shows a Southern blot of the 15-h sampling. A band of ~10 kilobases (kb) in the undigested DNA represents the linear form of unintegrated

Fig. 1 Southern blot²² analysis of unintegrated HTLV-III DNA. No viral sequences could be detected in the undigested DNA after 4 h. However, a major species of viral DNA ~10 kb long was present at 10, 15, 24 and 48 h, representing the linear unintegrated form of the virus. The figure shows a representative Southern blot of the 15-h sample digested with several restriction enzymes.

Methods: Fresh uninfected H9 cells (8×10^9) were infected with concentrated supernatant from cell line H9/HTLV-III containing 4×10^{11} particles of HTLV-III. Infected cells were divided into five roller bottles and collected after 4, 10, 15, 24 and 48 h. Low-molecular weight DNA was prepared using the Hirt fractionation procedure¹⁴ and 30 μ g of undigested and digested DNAs were separated on a 0.8% agarose gel, transferred to nitrocellulose paper, and hybridized to an HTLV-III cDNA probe for 24 h at 37 °C in $2.4 \times$ SSC, 40% formamide and 10% dextran sulphate. cDNA was synthesized from poly(A)-selected RNA prepared from doubly banded HTLV-III virus in the presence of oligo(dT) primers²³. Filters were washed in $1 \times$ SSC at 65 °C.

HTLV-III. No closed or nicked circular DNA could be detected at 10, 15 or 24 h, but both forms were evident in small amounts at 48 h (data not shown). The viral genome was not cleaved by *XbaI*, whereas *SstI* generated three predominant bands of 9, 5.5 and 3.5 kb (Fig. 1). We interpreted these bands as representing the genomes of two forms of HTLV-III, both cut by *SstI* in or near the long terminal repeat (LTR), and one having an additional *SstI* site in the middle of its genome. The other enzymes generated a more complex pattern of restriction fragments requiring cloned DNA for further analysis.

Figure 2 shows the restriction map of three clones, designated λ BH10, λ BH5 and λ BH8, which correspond in size to the three *SstI* fragments shown in Fig. 1. Comparison of these maps suggests that λ BH5 plus λ BH8 constitute one HTLV-III

Fig. 2 Restriction endonuclease map of two closely related HTLV-III forms cloned from unintegrated viral DNA. Three recombinant clones (λ BH10, λ BH5 and λ BH8) were analysed and their inserts (9, 5.5 and 3.5 kb, respectively) were mapped with the indicated enzymes. Together they represent two genomic equivalents of HTLV-III that are highly related but differ in three enzyme sites, indicated by bold letters and asterisks.

Methods: Low-molecular weight DNAs pooled from the 15- and 24-h samples were fractionated on a 10–40% sucrose gradient²³. Aliquots of the fractions were electrophoresed on a 0.5% agarose gel, transferred to nitrocellulose paper and hybridized to HTLV cDNA in conditions described in Fig. 1 legend. Fractions containing the unintegrated linear HTLV-III genome shown by hybridization

were pooled; the DNA was subsequently digested with *SstI*, then ligated to phosphatase-treated *SstI* arms of λ gtWes- λ B. After *in vitro* packaging, recombinant phages were screened for viral sequences with HTLV-III cDNA^{15,23}.

Fig. 3 Demonstration of the presence of HTLV-III viral sequences in the infected cell line, H9/HTLV-III. Both variant forms of HTLV-III defined by differences in *SstI* sites were detected in H9/HTLV-III DNA. No HTLV-III sequences were found in uninfected H9 cells, uninfected HT cells or normal human thymus (NT). **Methods:** High-molecular weight DNA (10 µg) was digested with restriction enzymes as indicated and hybridized to the nick-translated phage insert from λ BH10 in the conditions described in Fig. 1 legend.

genome, and λBH10 another. The two viral forms differ in 3 of 21 mapped enzyme sites, including the internal *SstI* site. As expected, the phage inserts of λBH5 and λBH8 hybridize in high-stringency conditions ($T_m = -25^\circ\text{C}$) to λBH10 but not to each other, as analysed by Southern blot hybridization and electron microscopic heteroduplex analysis (data not shown). To determine the orientation of the three clones, we used as a probe a cDNA clone (C15) containing U3 and R sequences (S.K.A. *et al.*, in preparation); C15 hybridized strongly to the 0.5 kb *BglII* fragment of λBH10 and λBH8, orienting this side 3'. Assuming that *SstI* cuts only once in the vicinity of the HTLV-III LTR, the clones λBH10 and λBH5/λBH8 represent two complete genomic equivalents of the linear unintegrated form of HTLV-III that vary in three restriction enzyme sites. However, the viral fragments cloned into λBH5 and λBH8 may have been derived from the same or two different viruses.

The presence of two variant forms of HTLV-III in the original cell line was demonstrated by hybridizing the radiolabelled insert of λBH10 to a Southern blot of H9/HTLV-III genomic DNA digested with several restriction enzymes (Fig. 3); both forms were detected using *SstI*, which generated the expected three bands of 9, 5.5 and 3.5 kb. *XbaI*, which does not cut the provirus, generated a high-molecular weight smear representing polyclonal integration of the provirus, plus a band of ~10 kb. This 10-kb band was also detected in undigested H9/HTLV-III DNA (not shown), indicating that it represents unintegrated viral DNA. The presence of unintegrated viral DNA also explains the 4- and 4.5-kb *EcoRI* fragments seen in both the Hirt and total cellular DNA preparations (Figs 1, 3). Both *BglII* and *HindIII* cut within the LTR and generate the expected internal bands. Several faint bands in addition to the expected internal bands generated by *HindIII* digestion, represent either defective proviruses or other variant forms of HTLV-III present in low copy number.

The absence of HTLV-III sequences from the DNA of the uninfected H9 cell line, the uninfected parental cell line HT and normal human thymus (Fig. 3), demonstrates clearly the exogenous nature of HTLV-III and shows that the virus does not contain human cellular sequences. The same results were obtained using inserts from λBH5 and λBH8 as probes.

The availability of the cloned HTLV-III genome also allowed us to evaluate sequence homology between HTLV-III and other members of the HTLV family including HTLV-I and HTLV-II,

Fig. 4 Sequence homology of HTLV-III to other members of the HTLV family. Schematic restriction maps of HTLV-I, HTLV-Ib and HTLV-II are shown at the bottom, indicating the length (in kb) and location of the generated fragments with respect to the corresponding genomic regions of HTLV-I. LTR, *gag*, *pol*, *env* and *pX* regions are drawn to scale according to the published nucleotide sequence of HTLV-I²⁴. The bands that are most highly conserved as stringency increases correspond to the *gag/pol* junction region of HTLV-I (1.8-kb *PstI* fragment) and HTLV-Ib (3.1-kb *PstI* fragment) and to the 3' part of the *pol* region of HTLV-II (2.1-kb *SmaI/BamHI* fragment) which do not overlap assuming that HTLV-II has a genomic organization similar to that of HTLV-I. Fragments corresponding to *pX* of HTLV-I (2.1-kb *SstI/PstI* fragment) and HTLV-Ib (1.4-kb *PstI* fragment) are only faintly visible at $T_m = -28^\circ\text{C}$ on the original autoradiogram. Digestion of GaLV generates six fragments, none of which hybridizes with HTLV-III in medium or high stringency conditions ($T_m = -42^\circ\text{C}$ and -28°C).

Methods: Subclones of full-length genomes of a prototype HTLV-I (unpublished), HTLV-Ib¹⁶, HTLV-II²⁵ and GaLV (Seato strain)²⁶ were digested with the following enzymes; *PstI* plus *SstI* (HTLV-I and HTLV-Ib); *BamHI* plus *SmaI* (HTLV-II); and *HindIII*, *SmaI* and *XhoI* (GaLV). Four replicate filters were prepared and hybridized for 36 h under low stringency (8×SSC, 20% formamide, 10% dextran sulphate at 37°C) to nick-translated insert of λBH10. Filters were then washed in 1×SSC at different temperatures: a, 22°C ($T_m = -70^\circ\text{C}$); b, 37°C ($T_m = -56^\circ\text{C}$); c, 50°C ($T_m = -42^\circ\text{C}$); and d, 65°C ($T_m = -28^\circ\text{C}$), and subsequently autoradiographed for 24 h.

as well as a variant of HTLV-I (HTLV-Ib) recently isolated and molecularly cloned from a Zairian patient with adult T-cell leukaemia¹⁶. Replicate Southern blots of restriction enzyme-digested clones comprising the complete genomes of HTLV-I, HTLV-Ib and HTLV-II, and of gibbon ape leukaemia virus (GaLV) as a control, were hybridized with the full-length HTLV-III probe (BH10) in relaxed conditions, after which the filters were washed in conditions of low, medium and high stringency (Fig. 4). This experiment demonstrates homology between HTLV-III and HTLV-I, HTLV-Ib and HTLV-II, but not between HTLV-III and GaLV. Hybridization of HTLV-III with other members of the HTLV family could be detected in conditions ($T_m = -42^\circ\text{C}$ and -28°C) where no hybridization to GaLV was seen (Fig. 4c, d). Note that the restriction fragments showing greatest homology to HTLV-III correspond to the *gag/pol* region of HTLV-I and to an apparently non-overlapping portion of the *pol* region of HTLV-II (assuming that the genomic arrangement of HTLV-II is similar to that of HTLV-I). Hybridization to a fragment containing exclusively *pX* sequences in HTLV-Ib (1.4-kb *PstI* fragment) and to the corresponding fragment in HTLV-I containing *pX* and LTR sequences (2.1-kb *PstI/SstI*) was detectable at $T_m = -28^\circ\text{C}$ but was very faint. *pX* sequences of HTLV-II did not hybridize to the HTLV-III probe in the same stringency conditions, nor did fragments containing LTR or envelope sequences of both HTLV-I and HTLV-II.

Overall, these findings using the cloned HTLV-III probe agree with our previous observations using HTLV-III cDNA¹⁵, which also revealed sequence homology, especially in the *gag/pol* regions of the HTLV-I, HTLV-II and HTLV-III genomes. However, we emphasize that HTLV-III is much less closely related to HTLV-I and HTLV-II at the nucleic acid level than HTLV-I and HTLV-II are to each other^{17,18} and that this homology is most evident in the *gag/pol* region of these viruses under stringent hybridization.

Thus, we have molecularly cloned two closely related but distinguishable genomic equivalents of HTLV-III from the H9/HTLV-III cell line, which has been the principal source for all viral reagents used in studies of the sero-epidemiology of HTLV-III in AIDS patients¹⁻⁷. Note that this virus from the H9/HTLV-III cell line retains its cytopathic activity against fresh normal human lymphocytes (unpublished data). Using these clones as probes, we also detected HTLV-III viral sequences in infected cell lines other than H9/HTLV-III that were established from different AIDS patients, and in fresh uncultured lymphoid tissues of AIDS patients¹⁹. These findings suggest that the cloned HTLV-III genomes reported here represent the probable aetiological viral agent of AIDS. The finding of two variant forms of HTLV-III in the H9/HTLV-III cell line could reflect cumulative *in vitro* mutations in a highly replicative virus. The two forms could also represent different isolates as, when first established, the H9/HTLV-III cell line was infected with pooled material from several different AIDS patients². Preliminary studies of other HTLV-III isolates indeed indicate that HTLV-III, unlike HTLV-I and HTLV-II, exhibits substantial diversity in its restriction enzyme cleavage pattern when isolates from different patients are compared¹⁹. Further characterization and sequence analysis will help to define the natural variability of this virus, which has important implications with respect to its pathogenicity and origin, and attempts at preventive measures for AIDS. The availability of the cloned HTLV-III genome should also now allow direct comparison of this virus with a similar group of retroviruses described by other investigators⁸⁻¹¹ which has also been linked to the pathogenesis of AIDS and which appears to be immunologically and morphologically indistinguishable from HTLV-III (M. Sarngadharan *et al.*, unpublished). Finally, the demonstration of a substantial amount of unintegrated viral DNA in the chronically infected cell line H9/HTLV-III, distinguishes HTLV-III from HTLV-I, HTLV-II and most other retroviruses. It will be important to determine whether the presence of unintegrated DNA has a role in the cytopathicity of HTLV-III, as has been proposed for certain other retroviruses^{20,21}.

Metabolic oxidation phenotypes as markers for susceptibility to lung cancer

Riad Ayesh*, Jeffrey R. Idle†, James C. Ritchie†, Michael J. Crothers† & Martin R. Hetzel*

* The Chest Unit, Whittington Hospital, London N19 5NF, UK

† Department of Pharmacology, St Mary's Hospital Medical School, Paddington, London W2 1PG, UK

That bronchial carcinoma is not an inevitable consequence of cigarette smoking has stimulated the search for host factors that might influence the susceptibility of the individual smoker. One plausible host factor would be a polymorphic gene controlling the metabolic oxidative activation of chemical carcinogens, giving rise to wide inter-subject variation in the generation of cancer-inducing and/or promoting species. Recently, three genetic polymorphisms of human metabolic oxidation have been demonstrated (as characterized by debrisoquine, mephenytoin and carbocysteine), with the metabolism of several substrates exhibiting the phenomenon¹⁻³. Debrisoquine 4-hydroxylation segregates into two human phenotypes, each comprising characteristic metabolic capability⁴⁻⁶. We report here the frequency of debrisoquine 4-hydroxylation phenotypes in age-, sex- and smoking history-matched bronchial carcinoma and control patients. Cancer patients showed a preponderance of probable homozygous dominant extensive metabolizers (78.8%) with few recessive poor metabolizers (1.6%) compared with smoking controls (27.8% and 9.0% respectively). We conclude that the gene controlling debrisoquine 4-hydroxylation may be a host genetic determinant of susceptibility to lung cancer in smokers and that it represents a marker to assist in assessing individual risk.

The metabolism of debrisoquine was examined in 479 cigarette smokers who had or had not presented with bronchogenic carcinoma, in order to determine the frequency of extensive metabolizer (EM) and poor metabolizer (PM) phenotypes in each group. Patients were recruited from areas of London within the Islington District, Bloomsbury District and Wandsworth District Health Authorities and were admitted primarily to Chest Unit beds at Whittington Hospital. All were white Europeans with a positive history of cigarette smoking (>20 pack-yr, that is, number of packs of 20 cigarettes per day × number of years of smoking). Subjects were excluded if chemotherapy or drugs known to interfere with the phenotyping test¹ had been given, if there were signs of abnormal hepatic or renal function and if additional acute conditions such as heart failure or severe chest infection obtained. The cancer patients ($n = 245$) had a definite diagnosis of bronchogenic carcinoma proven by histology (108), cytology (85) or histology/cytology (44) from samples obtained at bronchoscopy (194), transcutaneous needle biopsy (24), mediastinoscopy (9) and pleural biopsy (6). Cell types comprised squamous cell (138), small cell (68), large cell (8) and undifferentiated (1) carcinomas, together with 30 adenocarcinoma patients. Control patients ($n = 234$) were smokers with chronic airflow limitation, without evidence of carcinoma. Each patient received no drugs after 21.30 h the day before the test, nor for 2 h after the start of the test at 07.00 h. They were each given a 10 mg debrisoquine tablet orally; all urine was collected for the subsequent 8 h and analysed for its content of debrisoquine (D) and 4-hydroxydebrisoquine (4-HD) by electron-capture gas chromatography⁷. The metabolic ratio (urinary D/4-HD) thus determined was used to assign phenotype (EM, 0.1-12.6; PM, 12.7-100)⁵. Routine clinical chemistry and haematology were performed on a blood sample from each patient within 2 days before or after the test.

Cancer and control patients were similar in age (66.5 ± 7.4 ($\pm$ s.d.) and 67.2 ± 3.3 yr respectively), sex ratio (M/F) (1.82, 1.89) and smoking history (60.3 ± 24.0 , 59.4 ± 21.1 pack-yr). The results showed that the patients also had similar levels of plasma Na^+ (137 ± 6 , 137 ± 4 mM in cancer and control patients, respectively), HCO_3^- (27.0 ± 5.4 , 26.8 ± 4.9 mM), urea (5.0 ± 1.3 , $5.1 \pm$

Fig. 1 Distribution of metabolic ratios (urinary D/4-HD) in smoking controls (a, $n = 234$) and bronchogenic carcinoma patients (b, $n = 245$).

1.6 mM), total protein (70.5 ± 4.8 , 70.9 ± 5.0 g l⁻¹ and bilirubin (8.6 ± 8.7 , 8.0 ± 7.6 μ M), and comparable white cell counts (9.0 ± 3.2 , $8.7 \pm 2.5 \times 10^9$ l⁻¹), mean corpuscular haemoglobin concentration (32.7 ± 2.2 , 32.8 ± 2.0 g per 100 ml) and platelet count (321 ± 85 , $325 \pm 89 \times 10^9$ l⁻¹). Values for plasma K⁺, albumin, alkaline phosphatase, aspartate aminotransferase, haemoglobin, packed cell volume, mean corpuscular volume and mean corpuscular haemoglobin all showed small but statistically significant differences between cohorts, but nevertheless fell within the 'normal' clinical range.

Debrisoquine 4-hydroxylation, however, showed several major differences between cancer and control cohorts (Fig. 1). While the metabolic ratios for 'smoking' controls were distributed across the full range of values and included 21 recessives (values > 12.6), the metabolic ratios for cancer patients were aggregated towards the left end (rapid metabolism) of the spectrum, with only four recessives. Figure 2 shows the combined data in logarithmic form, which both compresses and normalizes the distribution. Analysis of family pedigrees and a similar distribution for a healthy white British population⁶ has allowed estimation of the mean ($\pm$ s.d.) log₁₀ metabolic ratios for homozygous EM, heterozygous EM and recessive PM genotypes as -0.26 ± 0.23 , 0.13 ± 0.33 and 1.44 ± 0.31 , respectively. Remarkably, the additive cancer and control distributions have major modes at -0.35 , 0.05 and 1.75 , which almost certainly correspond to the three genotypes (Fig. 2). Thus, most cancer patients with log₁₀ metabolic ratios of less than 0 (193/245; 78.8%) probably have homozygous dominant genotypes, whereas the majority of smoking controls (148/234; 63.2%) with log₁₀ values between 0 and 1.1 (Fig. 2; ratios 1–12.6 in Fig. 1) are probably heterozygotes. Probable homozygous individuals in the control group were 27.8% (65/234) EM and 9.0% (21/234) PM genotypes. Finally, inspection of the extremities of the distribution reveals not only that there are no controls with ratios of 0.1–0.2, but also that the PM mode is almost devoid of cancer patients. Of the four cancer patients with a PM phenotype, two were adenocarcinoma patients and one had a 150 pack-yr cigarette consumption.

Fig. 2 Distribution of log₁₀ metabolic ratios for cancer (solid bars) and control (open bars) groups combined.

Care has been taken to ensure similarity between the two cohorts for factors which could influence either the disease (age, sex, smoking history) or the phenotyping test (hepatic/renal impairment, ethnicity, recent drug history). Nevertheless, the question arises as to whether or not the metabolic differences between cohorts which we report here contribute to the cause of lung cancer or are a result of it. Several reasons support the former interpretation of these data. First, our own findings in patients with cancer at other sites such as colon, rectum and urinary bladder, suggest that the presence of a tumour has no effect on the phenotyping test. Also, the debrisoquine metabolic ratio arises from hepatic metabolism of the administered drug and therefore major pathological changes within the liver might be expected to perturb the phenotyping test more than any other disease state. Appropriate data from a population of alcoholics with liver diseases of varying severity show that this is not the case⁸.

We propose, therefore, that the metabolic and genetic differences between white European cigarette smokers in this study who developed lung cancer by, on average, their mid-sixties and those who did not, reflect the aetiology of the disease. Homozygous dominants appear to be at high risk of developing cancer, whereas heterozygotes and recessives are at relatively low risk.

Debrisoquine 4-hydroxylase may not be involved in chemical carcinogen metabolism, but its gene may flank others with oncogenic potential, recessives for which will almost certainly be recessives for debrisoquine 4-hydroxylation. Such genes might be structural or regulatory genes for cytochromes P450, such as the *Ah* locus⁹, or indeed genes not involved in chemical carcinogen metabolism, for example, cellular oncogenes. We conclude that the metabolic oxidation phenotypes serve as genetic markers for differential lung cancer susceptibility.

This work was supported by grants from the Cancer Research Campaign. J.R.I. is a Wellcome Trust Senior Lecturer. We thank Nick Oates for computer analysis of the data. We also thank the consultants at St James Hospital, Balham and The National Temperance Hospital who allowed us to study their patients.

Alu sequences are processed 7SL RNA genes

Elisabetta Ullu* & Christian Tschudi†

* Department of Molecular Biophysics and Biochemistry and

† Department of Internal Medicine, School of Medicine, Yale University, New Haven, Connecticut 06510, USA

7SL RNA is an abundant cytoplasmic RNA which functions in protein secretion as a component of the signal recognition particle¹. *Alu* sequences are the most abundant family of human and rodent middle repetitive DNA sequences (reviewed in ref. 2). The primary structure of human 7SL RNA consists of an *Alu* sequence interrupted by a 155-base pair (bp) sequence that is unique to 7SL RNA³. In order to obtain information about the evolution of the *Alu* domain of 7SL RNA, we have determined the nucleotide sequence of a cDNA copy of *Xenopus laevis* 7SL RNA and of the 7SL RNA gene of *Drosophila melanogaster*. We find that the *Xenopus* sequence is 87% homologous with its human counterpart and the *Drosophila* 7SL RNA is 64% homologous to both the human and amphibian molecules. Despite the evolutionary distance between the species, significant blocks of homology to both the *Alu* and 7SL-specific portions of mammalian 7SL RNA can be found in the insect sequence. These results clearly demonstrate that the *Alu* sequence in 7SL RNA appeared in evolution before the mammalian radiation. We suggest that mammalian *Alu* sequences were derived from 7SL RNA (or DNA) by a deletion of the central 7SL-specific sequence, and are therefore processed 7SL RNA genes.

The signal recognition particle (SRP) mediates the translocation of secretory proteins across the endoplasmic reticulum⁴⁻⁶. SRP consists of six different polypeptides and one molecule of 7SL RNA¹. Previous studies have shown that 7SL RNA is an essential component for SRP function¹.

In the human genome, *Alu* DNA constitutes the dominant family of short middle-repetitive mobile sequences⁷, and in addition, *Alu* equivalents have been described in the genomes of other primates^{8,9}, as well as in rodents^{10,11}. Human 7SL RNA is an abundant cytoplasmic RNA of 300 nucleotides which was shown to be partially homologous with *Alu* DNA¹². Approximately 100 nucleotides at the 5' end and 45 nucleotides at the 3' end of the RNA are homologous with the human *Alu* right monomer consensus sequence³. The central portion of 155 nucleotides shows no homology with *Alu* DNA and is unique to 7SL RNA (Fig. 1). The entire human and rodent *Alu* sequences are represented in the 7SL molecule (see Fig. 1).

Fig. 2 The nucleotide sequences of *Xenopus* and *Drosophila* 7SL DNA and their comparison with the human 7SL cDNA. The nucleotide sequence of a cDNA copy of *X. laevis* 7SL RNA (top line) and of the *D. melanogaster* 7SL RNA gene (bottom line) were determined by the chemical degradation²⁵ and the dideoxy-chain termination methods²⁶. The anticoding strand of both 7SL DNAs was aligned with the sequence of human cDNA clone 7L1 (ref. 3). The sequences are numbered with respect to the first nucleotide of the human 7SL cDNA. The first four nucleotides of cDNA clone 7L1³ are not included, because they are not represented in human 7SL RNA (E.U., unpublished observation). Asterisks denote homology between human 7L1 DNA and the amphibian or insect molecule, respectively. Dashes are occasionally introduced to maximize homology. The *Alu*-like portions of the human 7SL DNA are boxed.

Fig. 1 The structural relationship of human 7SL RNA to the consensus sequences of human and rodent *Alu* DNA. Homologous sequences are indicated by identical shading. Human *Alu* DNA is a head to tail dimer of two similar sequences ~130 bp long. The right monomer contains an insert (I) which is not present in the left half²³. The rodent *Alu* equivalent sequence is a monomer^{10,11}. We have found that the mouse B1 *Alu*-equivalent consensus sequence compiled by Kalb *et al.*²⁴ contains an internal tandem duplication of 30 bp between positions 62 and 121. The type I Chinese hamster *Alu*-equivalent sequence¹¹ has a similar structural arrangement. Arrows above the rodent *Alu* DNA indicate the position of the 30-bp tandem duplication; (A)_n denotes an A-rich sequence which follows the *Alu* sequence at the 3' end.

To obtain information about the evolution of 7SL RNA and its possible relationship to *Alu* sequences, we have analysed the 7SL sequence in *X. laevis* and *D. melanogaster*. A cDNA copy of *in vitro* polyadenylated 7SL RNA of *X. laevis* was prepared as described previously³. For *Drosophila*, a bacteriophage library of embryonic DNA was screened for sequences homologous to the 155-nucleotide portion of human 7SL RNA not homologous with *Alu* DNA, using the 125-base pair (bp) *Sau*3A fragment of clone p7L1 as a probe³. Restriction endonuclease mapping of three independent positive phage clones and subsequent sequence determination of appropriate DNA fragments established that there are two identical genes coding for 7SL RNA in *D. melanogaster* (C.T. and Jean Burckhardt, manuscript in preparation). Figure 2 compares the primary structures of the *Xenopus* and *Drosophila* 7SL DNA with the human counterpart. The length of the 7SL RNAs of *Xenopus* and *Drosophila* is comparable with that of human 7SL RNA, which agrees with the observation that the three 7SL RNAs have the same electrophoretic mobility¹³. However, we have not determined the

precise 5' and 3' ends of *Xenopus* and *Drosophila* 7SL RNA. The *Xenopus* sequence is strikingly homologous to the human one over its entire length. There is only a 13% divergence and the mismatches are distributed along the entire length of the molecule. As these two 7SL DNAs are extremely similar, the appearance of the *Alu*-like sequence in the 7SL RNA molecule evidently preceded the mammalian radiation in evolution.

When the sequence of the *Drosophila* 7SL DNA is compared with its human and amphibian counterparts, there is an ~64% homology; however, extended regions in the central 7SL-specific portion can be seen, where the sequences have been almost perfectly conserved. These 7SL-specific homologies may reflect a strong functional constraint acting on these sequences. The *Alu*-like portions of the human and insect 7SL DNA can be only poorly aligned. Nonetheless, the vestiges of the mammalian *Alu*-like sequence can be recognized in the *Drosophila* 7SL DNA. These results, taken together, strongly suggest that the evolution of the *Alu*-like portions of 7SL RNA has taken place gradually. No dramatic event such as the insertion of the 155-bp 7SL-specific DNA into a human *Alu* sequence, as originally suggested³, can account for the identical composite structure of 7SL RNA in two lower organisms. If 7SL RNA genes were in fact assembled from two different types of sequences, such an event must have occurred before the appearance of insects.

Because the structure of 7SL RNA has been extensively conserved in evolution, we propose that 7SL RNA genes represent the ancestor of the *Alu* sequence and that *Alu* DNA arose from the 7SL RNA information through a deletion of the central 7SL-specific sequence. Such a deletion could have occurred either at the DNA level (through non-homologous recombination within or between 7SL RNA genes) or at the RNA level (due perhaps to an aberrant RNA joining or splicing event).

The discovery of 'processed genes' which lack intervening sequences and closely resemble the mature mRNA structure¹⁴, and the finding of pseudogenes for the small nuclear RNAs¹⁵ have provided evidence that RNA information can flow back into the genome. We speculate that the prototypical *Alu* sequence is a processed 7SL RNA gene. It has been observed that the 7SL RNA molecule within SRP is very resistant to micrococcal nuclease digestion^{1,16}. Interestingly, only three major discrete RNA fragments are generated by limited nuclease digestion of SRP. Two fragments of 72 and 45 nucleotides span the 5' and 3' *Alu*-like portions, respectively, while the third product of nuclease cleavage spans the entire 7SL-specific sequence of the RNA¹⁶. These experiments clearly indicate that an enzyme probe can readily recognize the boundaries of the *Alu*-like and 7SL-specific domains of 7SL RNA in the intact ribonucleoprotein particle. This finding suggests that SRP itself may contain the RNA in a conformation which promotes excision of the 7SL-specific domain. Once this happens, the 5' and 3' *Alu*-like portions could be ligated together, generating a contiguous *Alu* RNA. The sequence of the spliced RNA could then have been re-integrated into the genome.

Several groups have proposed that processed genes could arise from the reverse transcription of cellular RNA species, followed by integration of the cDNA into new chromosomal sites in germ-line DNA^{14,17-20}. In this context, 7SL RNA was first discovered as a component of avian and murine retroviral particles²¹. Because retroviruses encode a reverse transcriptase and carry the enzyme within the virion, it is tempting to speculate that retroviruses are responsible for the generation of an *Alu* sequence from 7SL RNA.

Using the homologous 7SL DNAs as probes, we have searched in the genomes of *Drosophila* and *Xenopus* for 7SL RNA-related sequences (data not shown). We note that the *Drosophila* genome contains only two 7SL RNA genes and no other cross-hybridizing sequences. In contrast, *Xenopus* DNA is rich in sequences capable of cross-hybridizing to the homologous 7SL DNA probe. Some of these sequences might represent *Alu*-like sequences, as suggested by previous studies²². It is possible that the excision of the *Alu* sequence from 7SL RNA (or DNA) may have occurred several times in evolution. Once freed of 7SL

sequences, *Alu* DNA may no longer be subject to the functional constraints which operate on the 7SL RNA genes and thus may be capable of evolving independently from 7SL RNA.

We thank Jean Burckhardt for making the *Drosophila* 7SL recombinant clones available to us, Alan Weiner and Frank Richards for advice and support, Peter Walter for his continuous interest, Alex Young for technical assistance and Manny Ares, Joan Steitz, Peter Walter and Alan Weiner for critical reading of the manuscript. E.U. was the recipient of a long-term EMBO fellowship and is on leave of absence from the Istituto di Biologia Generale, Università di Roma. This work was supported in part by NIH grants GM 31073 and GM 31335 to Alan Weiner and AI 08614 to Frank Richards.

W.F. Bynum

The Discoverers: A History of Man's Search to Know His World and Himself.

By Daniel J. Boorstin.

Dent/Random House: 1984. Pp. 768. £15, \$25.

DANIEL Boorstin has been Librarian of Congress since 1975 and his previous dozen books (including one Pulitzer Prize winner) have been on American history. *The Discoverers* is his homage to the rest of the world. America and Americans are of course part of his story, but only a relatively small one. His primary focus is Europe and Asia and those who have contributed to "man's search to know his world and himself".

The book's sub-title and size suggest that Mr Boorstin has set himself a task on the grand scale. A look at the volume's four main sections confirms this: "Time"; "The Earth and the Seas"; "Nature"; "Society". This organization provides a rough chronological thrust to his narrative. "Time" deals with ancient calendars, seasonal reckoning and time-telling from antiquity to the coming of clocks and watches. John Harrison's chronometer for calculating longitude links that section with the next, which examines cosmology and cartography, navigation and exploration, from long before Ptolemy to long after Columbus. The section on Nature takes off from the Scientific Revolution, when the telescope and microscope extended the range of vision, and makes its leisurely way through some of the principal scientific disciplines of the eighteenth and nineteenth centuries, such as taxonomy, palaeontology and evolutionary biology. Finally, "Society" describes a fascinating mélange of topics, from printing and books to the writing of history, the discovery of Troy and Keynesian economics.

The result is both less and more than a conventional history of science. It is less because the coverage is sometimes patchy, particularly of the physical sciences after Newton. There is virtually nothing on chemistry (Lavoisier rates only one passing mention) and two centuries of physics are covered in a rather unfortunate closing chapter (part of "Society", not "Nature") in which Mr Boorstin leaves himself only a single page to dispense with James Clerk Maxwell, J.J. Thomson, Ernest Rutherford and Albert Einstein. Seventeenth-century microscopists such as Leeuwenhoek and Malpighi get full treatment, but there is nothing on cell theory of the nineteenth century. Galen, Vesalius, Paracelsus and Harvey (mistakenly knighted on p. 459) get their due, but virtually no doctors after them except for Freud.

Mr Boorstin has therefore not given his

readers much that a single-volume survey of the history of science and scientific discovery should; but he has more than compensated for this lacuna by offering a great deal more. Scattered through this magnificent volume are unexpected themes and people treated with what can only be described as affectionate authority. The Jesuits and their clocks in China; Islamic attitudes to the printing press; the growth of public libraries; the discovery of "prehistory": these and dozens of other vignettes share centre stage with a multinational cast of unfamiliar characters, such as Sir Anthony Panizzi, Italian-born librarian of the British Museum; Martin Waldseemüller, the German clergyman who named America; Chêng Ho, the eunuch Chinese navigator; and Lorenzo Valla, the Italian theological scholar. If the book contains many curious and delightful byways, seekers of more familiar discoveries and discoverers will not be disappointed, for individuals such as Copernicus and Galileo, Henry the Navigator and James Cook, Linnaeus and Darwin, are sympathetically covered. The level of accuracy throughout is unusually high in a book which covers such a vast terrain. A 30-page bibliographical essay guides the reader to the range of sources from which material has been drawn.

Mr Boorstin seems particularly to enjoy biography, and most of the book's 82

chapters are arranged around the achievements of two or three relevant people. This penchant for biography can be seen by the frequency with which he uses biographical metaphors and similes: Karl Marx was "a latter-day Paracelsus", Paracelsus in turn was "a medical Don Quixote". Newton was "the Galahad of the Scientific Quest", whereas several individuals (John Dalton, for example) were Columbuses. Boorstin has a fine eye for anecdote, is particularly good on word derivations (among them "punctual", "travel", "hour", "Bible", "culture") and writes always with elegance and zest. The volume is studded with memorable phrases and epigrams. One such epigram, not directly from his pen but quoted from Callimachus (305–240 BC), head librarian in Ptolemaic Alexandria, declares that "A big book is a big nuisance". If this is true, *The Discoverers* is the exception that proves the rule, for, like the Bible, this is a Good Book. It is best read slowly and in small doses, in order to savour the richness of the story. It is also best read with an historical atlas nearby, for despite the importance of geographical exploration among Boorstin's themes, there are no maps provided. Astronomical diagrams would also have helped readers grasp the differences between the cosmologies of the Babylonians, the Indians, Ptolemy and Kepler.

This book had its origins, Mr Boorstin tells us, in his first visit to Florence a half-century ago, and has been 15 years in the specific researching and writing. This long gestation has produced a splendid brain-child, a wise and optimistic volume which enlightens and entertains. Read it. □

Sprung from chains

Struther Arnott

Principles of Nucleic Acid Structure.

By Wolfram Saenger.

Springer-Verlag: 1984. Pp. 556. Pbk DM 79, \$29.50.

FROM time to time one reads a book or an account of an experiment and wishes, with more pleasure than envy, that one had produced it oneself. Wolfram Saenger's book is such a virtuoso production: well-written, profusely illustrated and astonishingly comprehensive. In it, fact and hypothesis are distinguished with rare scrupulousness. Any serious student or researcher will find it a mine of information. The merely curious now have a guidebook with which safely to explore the labyrinth of DNA and RNA structural studies.

Particularly praiseworthy is the way Saenger has managed to deal thoroughly but interestingly with all the fundamental business of conformational nomenclature and crystallographic esoterica. He has not failed to explore the many structural hypotheses still twisting slowly in the wind, but almost nowhere does he confuse these with experimentally well-founded models.

About a third of the book is devoted to exploring the nature and provenance of the polymorphism of DNA and RNA. Any polymer constructed with residues as complex as nucleotides should be extremely polymorphic. Even when restrained in plectonemically wound duplexes, with bases paired and stacked, polynucleotides have many degrees of structural freedom. Yet polymorphism in DNA and RNA structures has been persistently ignored or belittled, as a brief glance at history will show.

Astbury's early fibres were mixtures of A-DNA and B-DNA, but he interpreted their X-ray patterns in terms of a single allomorph with the residue repeat of B-DNA (0.34 nm) and the structural repeat of A-DNA (2.80 nm). Then, during the renaissance of X-ray studies in the early 1950s, Franklin and Gosling established that DNA was at least dimorphic. Provocatively, they named their newer form A, and the form worked on earlier by Wilkins, B. During the long process of reconciling the Watson-Crick hypothesis with a tangible structure, attention was focused on the more hydrated B form, and A-DNA was forgotten until the 1960s when RNA duplexes were discovered to have A-like structures. Despite conformational similarities the A structures are quite polymorphic, with helix pitches ranging from 2.8 nm to 3.9 nm and major grooves of strikingly variable widths. In the eponymous A-DNA this groove is clenched shut, excluding even water molecules, while in the A duplexes of largest pitch the

major groove is wide enough to accommodate a third polynucleotide chain. B-DNAs have been shown to be just as polymorphic with pitches ranging from 2.4 nm to 3.6 nm.

With Polonius-like retrospective wisdom one would expect the apotheosis of A and B polymorphism to be heteronomous duplexes in which one chain carries C3'-endo-puckered deoxyribose rings like the A structures and the other carries C2'-endo-puckered rings like B. The synthetic duplex poly d(A).poly d(T) indeed has such a structure. (Sadly this particular allomorph arrived too late to catch the Saenger omnibus.) Heteronomous duplexes, unlike allomorphs with identical chains, are highly polar. Perhaps bidirectional sequences on DNA in chromosomes function as valves or direction markers.

Clearly the great variety of (right-handed) helical structures trapped in fibres before 1980 implies at least as great a variability in DNAs and RNAs in other milieux. Saenger's book certainly exposes us to variety in the catalogue of static structures, but the lively world of nucleic acids, rich in movement, bending, breathing, vibrating and shimmering is largely unexplored. Perhaps the *frisson* of the discovery of left-handed DNA will emphasize the reality of polynucleotide variety and variability — but perhaps not!

The possibility of left-handed polynucleotide duplexes was recognized early on: Maurice Wilkins explored sinister

models of A- and B-DNA in the 1950s; later, others touted left-handedness for the D form of poly d(IC).poly d(IC), in hope, but erroneously. When a left-handed (Z) allomorph was eventually observed, ironically it indeed needed alternating purine-pyrimidine sequences. Z-like conformations have been observed with d(GC)_n.d(GC)_n, d(AC)_n.d(GT)_n and d(As⁴T)_n.d(As⁴T)_n but not yet with d(IC)_n.d(IC)_n — nor with d(AT)_n.d(AT)_n.

Depressingly, DNA is again being discussed in dimorphic terms; however now it is B and Z, not A and B! But Z-DNA is polymorphic too: relatively underwound duplexes with the peculiar dinucleotide motif of Z-DNA exist with residue rotations of 0°, -25°, -51° as well as the -60° of the first left-handed structure.

Current X-ray structural studies focus on oligonucleotides in single crystals and in poly(oligonucleotides) in fibres. These structures are less regular. Whether or not the excursions from regularity are related to base sequences is a lively issue. More ambitiously — and perhaps more wisely — there are increasingly successful studies of DNA bound to histones and other proteins which will reveal specifically how variety and variability in the genetic material can be exploited biologically. Among all its other riches, Saenger's book makes us aware of these too. □

Magnetic mixture

D. Walton

Rock and Mineral Magnetism.

By W. O'Reilly.

Blackie/Chapman & Hall: 1984. Pp.220. £19.50, \$45.

A number of texts on rock magnetism have appeared over the past 20 years, but there is still a clear need for a solid, carefully written book on the subject. Sadly, this contribution does not fit the bill.

In general, the objective of books of this nature is to provide geophysicists with the information to be able to understand how the magnetic vector is produced in their samples. To do this it is essential first to understand the mineralogy, that is, the chemical and physical properties of the magnetic minerals and how these can change with temperature, pressure and chemical environment. Second, it is necessary to understand the physics — how the magnetic moments of individual grains arise, and how assemblies of such grains produce the resultant magnetic vector of the sample given the conditions of temperature, magnetic field, cooling rate and so on to which the sample was exposed.

Dr O'Reilly certainly meets the first of

these goals. There is a wealth of useful information on the mineralogy of magnetic minerals; and while it is quite difficult to find the desired data, the fairly complete index mitigates the problem to a great extent.

Just as certainly, however, the book falls short of the second requirement: the mathematics is quite inadequate, with formulae simply being presented with no derivation and often supported by no reference. The equations are not numbered, often they are not displayed, simply appearing in the body of the text. Furthermore, the author is not only selective in his choice of references (perhaps understandably), but much of the literature he has opted to quote is oversimplified to such an extent that it is wrong. For example only one of Neel's famous papers is referred to, although these contain the basic physics and have not been superseded.

Neel's papers still form the basis for all rock magnetic theory. In discussing the physics of the subject, authors of textbooks would be well advised to begin with them. And if they intend to provide an accurate and reliable source of information for the uninitiated, it might be safer to end with them. □

D. Walton is Professor of Physics at McMaster University, Hamilton, Ontario.

Making a meal of primate ecology

R.D. Martin

Adaptations for Foraging in Nonhuman Primates: Contributions to an Organismal Biology of Prosimians, Monkeys, and Apes.

Edited by Peter S. Rodman and John G.H. Cant.

Columbia University Press: 1984. Pp. 351. Hbk \$45.50; pbk \$18.50.

FOR sound ecological reasons, field-studies of non-human primates have increasingly focused on quantitative studies of feeding behaviour (taken in the widest sense). Food provides the energy required for all activities, but collection incurs a cost, particularly in terms of locomotor energy expenditure, and the overall cost-benefit equation is clearly of central importance in our understanding of the behavioural ecology of any species. That equation, however, contains a large number of different variables and thus a wide-ranging approach to it is necessary.

Adaptations for Foraging in Nonhuman Primates, a collection of 11 chapters edited by Peter Rodman and John Cant, brings together accounts of a variety of different aspects of primate feeding adaptations with this end in mind. The book is, in fact, the outcome of a special symposium on primate "foraging" held at the annual meeting of the American Association of Physical Anthropologists in 1980.

Rodman and Cant have taken an extremely broad view of primate feeding adaptations, including a great number of morphological, physiological and behavioural components. Clearly, an integrated approach to all of these components is much to be desired. This is certainly true with respect to evolutionary biology, and it is gradually being recognized that it is also likely to apply to behavioural ecology.

To take just one example, abundantly illustrated in the book: Kleiber's Law governing the scaling of basal metabolic rate has far-reaching implications for morphology, physiology and behaviour, because of its direct relevance to energy budgets. Complex feedback relationships are involved and explanatory models are really inadequate without some appreciation of them. In leaf-eating primates, for instance, the overall energy budget depends not only on behavioural factors, but also on special adaptations in morphology (such as enlargement of part of the digestive tract to house a flourishing gut flora) and in physiology (such as possession of special physiological capacities for coping with plant secondary compounds). Indeed, it now seems likely that most or all leaf-eating primates exhibit relatively low basal metabolic rates, after body size has been taken into account, and this con-

stitutes part of their overall "strategy". Some of this interdependency is neatly illustrated in Milton's thoughtful chapter on the role of food-processing factors in primate food choice.

There is, of course, a problem involved in taking such a wide-ranging view of the subject. It is all very well being presented with series of tasty dishes; at the end of the meal, digestion must be feasible. In this respect, comparisons are bound to be made with *Primate Ecology*, edited by Tim Clutton-Brock and published by Academic Press in 1977, which very effectively brought together the results of a score of good, quantitative field studies of primate feeding behaviour, but which devoted little attention to morphology, physiology or locomotor behaviour.

Some of the chapters in the present volume are gems in their own right, either as useful syntheses or as accounts of new developments. Among the former, Kay's chapter on morphological correlates of feeding behaviour is especially noteworthy in bringing together several different lines of (predominantly dental) evidence that permit quite reliable inferences to be made about broad dietary habits from anatomical features. This has evident benefits for the interpretation of primate fossils, but the link with energy budgets of living primates is somewhat tenuous.

Of the contributions dealing with novel approaches, Milton's chapter centres on a broad, cross-species comparison of transit times for food material passing through the gut. This adds a new dimension to studies of gut parameters in relation to primate dietary habits. Two further chapters examine locomotion in specific relation to feeding behaviour; Crompton reports on a study of two bushbaby species in South Africa, while Garber describes a study of Geoffroy's tamarin in Panama. Both accounts are notable for their admirable emphasis on quantitative data and for their careful extraction of points for an explanatory framework. Although it is argued in other chapters that there is no clear relationship between diet and locomotor patterns across species, these two studies definitely demonstrate that locomotion is intimately related to food-gathering within species.

A number of authors here use comparisons of two species in order to investigate underlying relationships. The most suc-

New in paperback

● *Geographical Ecology: Patterns in the Distribution of Species* by Robert H. MacArthur, which first appeared in 1972. Publisher is Princeton University Press, price is \$19.50.

● *God and the New Physics* by Paul Davies. In the United States the paperback edition is published under the imprint of Touchstone Books, in Britain as a Pelican. Price is \$7.95, £3.95. For review see *Nature* 305, 833 (1983).

● *The Evolution of Human Consciousness* by John H. Crook. Publisher is Oxford University Press (Clarendon). Price is £9.95.

cessful of them is Waser, who compares two mangabey species. His chapter is actually most remarkable for its careful documentation of the close similarity in behavioural ecology between the arboreal mangabey species (*Cercocebus albigena*) that he studied in Uganda and the largely terrestrial species (*C. galeritus*) studied by Katherine Homewood in Kenya. Waser attempts to relate the relatively limited differences between the two species to ecological differences, but it is somewhat difficult to test the inferences made. This problem is even more acute with other chapters based on a comparison between two species. For instance, Temerin, Wheatley and Rodman attempt to analyse the relationship between body size and foraging in primates by comparing *Macaca fascicularis* (the crab-eating macaque) with *Pongo pygmaeus* (the orang-utan). These two primates do, of course, differ in numerous ways, but a comparison between them cannot reliably reveal which of those differences is due to body size alone. (Curiously, the book includes no allometric analyses other than those contained in Kay's chapter; this technique has much to offer, especially in identifying body-size effects.)

Finally, special mention should be made of Post's essentially theoretical, but

nonetheless challenging chapter arguing that current optimal foraging models are generally designed for fine-grained habitat conditions and are therefore inadequate for interpretation of primate feeding behaviour in patchy habitats.

Perhaps the most surprising point about the book as a whole is that there is no explicit discussion of the crucial distinction between "foraging" (the search for food) and "feeding" (actual ingestion). These terms are very loosely used in the literature and a clearing-up exercise is long overdue. But the book's principal drawback resides in its lack of cohesiveness; in the event, the meal is pretty indigestible. The introduction by Rodman and Cant is interesting in a historical sense, but theoretically superficial, while the closing chapter by Cant and Temerin, which could have served to bring the key points together, actually dissolves into a diffuse listing of large numbers of potential interacting variables. So although *Adaptations for Foraging in Nonhuman Primates* contains much of value in terms of individual chapters, it falls far short of the synthetic view of primate feeding adaptations that should one day emerge. □

Piecing it together

John M. Charap

The Ideas of Particle Physics: An Introduction for Scientists.

By J.E. Dodd.

Cambridge University Press: 1984. Pp. 202. Hbk £22.50, \$44.50; pbk £8.95, \$18.

THE IDEAS of particle physics are probably no more difficult than those of many other sciences, but they are certainly less familiar. Notwithstanding the fact that the discoveries of recent years together represent one of the great achievements of modern science, most non-physicists would be hard pressed to explain why there is such confidence in the validity of the "standard model" of electroweak and QCD interaction between leptons and quarks, still less to point beyond present frontiers to more or less credible speculation.

There has long been a need for a book which would enable scientists from other disciplines to share more fully in the continuing endeavour of particle physicists, pursued on a grand scale and addressing the most fundamental question about the ultimate structure of matter; after all, the advances of the past few years have brought about as profound a revolution of our knowledge of the basic constituents of all matter and of their interactions as did the heroic work of Bohr and Rutherford for our understanding of the constitution of atoms. Dr Dodd has written just such a book.

The stage is set with a brief introduction to the key ideas of relativistic quantum field theory, and the drama is allowed to unfold in a broadly chronological sweep. The mathematical demands are modest. Equations are used to summarize or to illustrate rather than to advance arguments. Diagrams likewise are there to elucidate and not to baffle, and the ubiquitous Feynman diagrams need hold no terror. The fact that there are rules which relate them quantitatively to measurable observables is mentioned but no such calculations are undertaken. And the book is bang up to date; the evidence for the top quark from the CERN $p\bar{p}$ collider is the only major post-publication discovery omitted.

If you consider yourself to be reasonably numerate, and want to learn about quarks and gluons, asymptotic freedom and colour confinement, electroweak unification, and W and Z bosons, Dr Dodd's book is an excellent place to start. More important, if you want to know how the jig-saw puzzle seems to be falling into place, making sense of the plethora of particles, then this is the book to read. □

John M. Charap is Professor of Theoretical Physics and Dean of the Faculty of Science at Queen Mary College, University of London.

Hows (and whys) in molecular biology

Peter Little

Transcription and Translation: A Practical Approach.

Edited by B.D. Hames and S.J. Higgins. IRL Press: 1984. Pp. 328. Pbk £12, \$24.

ONE of the problems of compiling a practical manual in molecular biology is to decide when to do it. The speed with which the subject progresses makes it difficult to judge when a method has progressed from research topic to established procedure. Perhaps the easiest way to identify areas that are ripe for such a treatment is to ask whether justification for use of the method has to be supplied with the protocol.

By this criterion, a number of the topics covered in Hames and Higgins's collection of articles were not ready for inclusion in a methods handbook. The point is most apparent in the first half of the book, which covers eukaryotic transcription and translation. Extensive protocols are provided in an annoying tabular form but they are heavily interspersed with results and discussion — this is particularly true of the chapter on expression of DNA in mammalian cells from Spandidos and Wilkie, who have otherwise written an interesting and extensive review of a rapidly developing field.

The second half of the book is devoted to

prokaryotic transcription-translation systems and eukaryotic *in vitro* methods and is a useful source of protocols, albeit in the same unsatisfactory format. Here Colman contributes a helpful and informative account of the use of *Xenopus* oocytes for translation of nucleic acids. Sandwiched between the two halves is a chapter on the use of *E. coli* polymerase to transcribe chromatin — a field which seems to me, even after reading this chapter, to have limited intellectual justification in view of extensive progress in *in vitro* techniques for faithful transcription of DNA by eukaryotic polymerases (well documented here by Manley).

It is worth comparing this volume with *Molecular Cloning: A Laboratory Manual*, published by Cold Spring Harbor Laboratory (reviewed in *Nature* 300, 782; 1982). The most striking difference is that in the latter book each method is presented clearly, without detailed discussion as to why one would want to make, for example, a phage lambda library. If the editors could have put together a manual on transcription and translation in a similar fashion, they would have produced a very worthwhile publication, but it is probably a few more years before this can be done. As it is the book contains several useful articles, but it is not one which I would buy for my laboratory. However, I think I would borrow it! □

Peter Little is a Staff Scientist at the Institute of Cancer Research, Chester Beatty Laboratories, London.

Cellular and other biologies

Many of the major laboratory equipment manufacturers are exhibiting at the current meeting of the American Society for Cell Biology.

● Newly introduced at the American Society for Cell Biology Meeting, the Dapple Systems, Inc. Video Image Measurement System (VIMS) performs direct on-screen measurement of features in video images produced by a camera mounted on a light or electron microscope or simply viewing a photograph. The video image and computer display are superimposed on a single monitor to allow marking of features. Measurement modes include outlining the periphery of features, tracing lengths, or making end points. Extensive statistical analysis programs report mean and variance, find comparisons between variables, and provide linear, log or polynomial fits. Distribution plots of one variable as a function of another are useful for studying correlations between two variables. The method of DeHoff and Rhines is employed to obtain distributions for the case of intersections of a planar surface through a solid with embedded features.

● The Labconco RapidStill III is a compact automatic steam distillation unit used for nitrogen/protein determinations. Operation is completely automatic. After pressing the start button, the distillation process is controlled by a timer that determines the amount of water and sodium hydroxide used. One distillation takes less than 4 minutes. The distillation system automatically shuts down when the adjustable timer goes off.

Circle No. 101 on Reader Service Card.

Fold-up scissors from B-J Scientific

● B-J Scientific Products of Albany, Oregon has introduced a compact, high-quality folding scissor called Slip-N-Snip, for use in the medical and scientific professions. These scissors are fabricated with stainless surgical steel blades and chrome-plated metal handles, and can actually cut through metal sheet with no damage to the blades. When not in use, Slip-N-Snip scissors can be easily folded up, with the blades completely shielded, and can be carried in a pocket with complete safety, unlike standard scissors.

Circle No. 102 on Reader Service Card.

● RepliPlate is a new colony transfer pad for the rapid replica plating of bacterial colonies, from the BioProducts Department of Marine Colloids Division, FMC Corporation. Each pad is presterilized and ready-to-use. At least six precise replications can be made in a matter of seconds. RepliPlate pads simplify multiple-colony replication or library screening and are compatible with normal aseptic laboratory techniques. The pads are disposable to ensure biohazard containment and to prevent cross-examination.

Electron micrograph of fibrillar collagen reconstituted from Vitrogen 100. Magnification $\times 30,000$.

● Vitrogen 100, the purified collagen for use in cell culture and biochemistry may now be purchased directly from Collagen Corporation of Palo Alto, California. Vitrogen 100 is a convenient, consistent and reproducible source of collagen which is economical to use. It is sterile, enzyme-solubilized bovine dermal collagen which has been extensively purified (99.9% pure), rigorously characterized and packaged for immediate use. Vitrogen 100 also eliminates problems with contaminants and batch-to-batch inconsistencies.

Circle No. 104 on Reader Service Card.

● Pharmacia Fine Chemicals has introduced four new columns for high-performance preparative chromatography of proteins with sample loadings of up to 500 mg. The columns are based on the monodisperse ion exchangers Mono Q (anion exchanger) and Mono S (cation exchanger) with bed volumes of 8ml, Mono Q HR 10/10 and Mono S HR 10/10, or 20ml, Mono Q HR 16/10 and Mono S HR 16/10. Resolution is the same as is obtained in the well known columns, Mono Q HR 5/5 and Mono S HR 5/5, at sample loadings which are up to 20 times greater. Scale is direct with well described scaling factors which makes methods development straight forward and reliable. The columns are supplied for direct connection to the Pharmacia FPLC System. Accessories for hook-up to other HPLC systems are available.

Circle No. 105 on Reader Service Card.

● ExpertVision, a new microcomputer-based system from Motion Analysis Corporation, allows the intricate movements of everything from microscopic organisms to human beings to robots to be analysed in detail. ExpertVision automatically converts images captured on videotape to a form that can be quickly analyzed by a computer. The system uses the video camera to capture images in real time. These analog video images are then played into a proprietary video processor that digitizes the image outline and inputs the data into a 16-bit, UNIX-based, high-resolution graphics workstation. The video processor displays the raw or processed images on the monitor, giving the operator immediate visual feedback. Once the digitized image is stored on the workstation's 42-megabyte hard disk, ExpertVision's software transforms the raw data into graphic images that depict the path of the motion. The digitized data are then analysed by a 16/32-bit microprocessor. The analysis can be displayed as numeric tabulated summaries, in graphic form (line graphs, bar charts, and three-dimensional images), or both. Hard-copy output of all screen displays can be generated on the system's printer/plotter.

Electrophoresis for nucleic acids — American Bionuclear's two new systems.

● Designed primarily for nucleic acid analysis, the new American Bionuclear SHU-1000 (14 $\times$ 20 cm gel dimension) and SHU-2000 (20 $\times$ 20 cm) are versatile horizontal gel electrophoresis systems. Both models feature sliding gates adjacent to the end of the gel bed for pouring agarose gels in the removable ultraviolet transparent tray or directly onto the gel platform. An integral cooling chamber located beneath the gel bed ensures a constant gel temperature during runs. Ports on each reservoir permit recirculation of buffer to minimize changes in pH or ionic strength during separations. The SHU-1000 and SHU-2000 feature a levelling base and a choice of a wide variety of polycarbonate combs.

● Laboratory Computer Systems, Inc. has added statistical analysis software to its Micro-Plan II image analysis system. The software is suitable for use with the IBM PC or PC/XT. The Micro Plan II is a low-cost, tablet-oriented image analyser that performs measurements such as length, area, centre of area, form factor, feret x-y, and maximum diameter of two-dimensional features traced on the digitizing tablet. The software allows the Micro-Plan II user to analyse these measurements statistically and to create data files in special formats that can be used for publication or read by Lotus Development Corporation's spreadsheet program 1-2-3. **Circle No. 108 on Reader Service Card.**

● Cambridge Isotope Laboratories is now offering carbon-13 labelled standards for the higher chlorinated homologue of the dioxin series. The particular standards are 1,2,3,4,7-pentachlorodibenzodioxin, 1,2,3,4,7,8-hexachlorodibenzodioxin, 1,2,3,4,7,9-heptachlorodibenzodioxin and 1,2,3,4,6,7,8,9-octachlorodibenzodioxin. Each standard is completely labelled with carbon-13 at an enrichment level of 99% or greater giving a net mass spectrometric response of + 12 AMU. Each standard is supplied at a specific concentration in nonane solution. The unlabelled standards of these same isomers are also available in standard solutions. Stable isotope labelled standards are already available for 2,3,7,8-tetrachlorodibenzodioxin and 1,2,3,4-tetrachlorodibenzodioxin. The addition of the penta through octa standards now makes it possible to do accurate GC/MS analyses on the whole series of most important dioxin isomers.

Hoefler's new gradient makers.

● A recent addition to the Hoefler Scientific range of small gradient makers is a 500-ml model, the SG107S. The capacity of the SG107S makes it suitable for pouring ten or more 14 x 16 cm slab gels collectively in the Hoefler multiple casting chamber, the SE615. The SG107S can also be used for generating buffer gradients in column chromatography. Like the smaller Hoefler gradient makers, this one is made from sturdy acrylic. A simple-to-operate push-pull valve connects two cylindrical chambers which are mounted on a flat acrylic base. A side outlet port at the base of the mixing chamber may be connected to a pump to control the flow rate. Mixing is done on a magnetic stirrer.

The LKB fraction collector for liquid chromatography.

● LKB-Produkter AB of Sweden has developed a new fraction collector, the 2212 HeliRac, for liquid chromatography. This microprocessor-controlled fraction collector uses circular racks. A wide range of tube sizes can be accommodated and three different collection modes (time, drop and pump signals) are available. Up to six time windows can be programmed for selective collection of peaks with known retention times. HeliRac has a rapid tube change time and is able to synchronize tube change with drop frequency to completely eliminate drops falling between tubes. The instrument case and keyboard are leakproof and resistant to most common solvents. Optional steel racks and a safety tray are available for the collection of aggressive solvents. An optional flow diverter can be used to divert unwanted eluent to a separate container. The collector can be used to control (via an interface) up to three pumps and three valves for automatic buffer changing.

Circle No. 111 on Reader Service Card.

● The Packard Model 1700 sample processor is a programmable digital diluter with a wide variety of applications. The two modules, diluter and keyboard, perform functions which include pipetting, diluting dispensing and multiple dispensing, sample only transferring, sample aliquoting, serial diluting and titrating. The diluter is driven by a Z-80 microprocessor and can communicate with other instruments via its RS232 port found on the back of the instrument. The keyboard, one 12-button keypad and four command keys, allow the user to communicate with the diluter. A touch-sensitive membrane overlay protects the keyboard from chemical spills. An eight character alphanumeric vacuum fluorescent display shows program information, memory location, and error codes. The movable keyboard module is attached to the sample processor by a flexible cord and can be positioned for the operator's convenience. The instrument will accommodate syringes of various sizes to maximize flexibility. The aspirate syringe pipettes sample or reagent, and the reagent syringe draws in the reagent that is to be dispensed.

Circle No. 112 on Reader Service Card.

Enzyme-linked immunosorbent assay plates can be washed on the Model 260 from Cambridge Technology.

● The Model 260 Platewasher from Cambridge Technology, Inc. of Cambridge, Massachusetts is now available with an optional wash manifold that permits as many as four different wash fluids to be used with the instrument without requiring manual change of tubing connections. The Model 261 manifold is constructed of high density polyethylene. No lubrication is required and the materials are compatible with most common wash fluids such as water, saline, alcohols, and trichloroacetic acid. The Model 260 Platewasher is designed to be used with EIA/ELISA procedures. It is a semi-automated system for washing the wells of microtiteration plates. The flow to each of the 24 wash needles is controlled individually and simultaneously, providing high well-to-well uniformity and making the unit much faster than manual techniques.

Circle No. 113 on Reader Service Card.

● Ultra-pure standards and standard mixtures for performing EPA 600 methods by gas chromatographic analysis are now available from Ultra Scientific. Each kit contains 1ml of each standard required for the particular method plus 1ml of a mixture. Individual standards are supplied in sealed 1ml ampules. Standards are prepared in solution, ready to use and guaranteed to specification. No additional preparation or handling of these hazardous materials is required. Free samples of standard mixtures for any EPA method from 600 to 612 are available on request from Ultra Scientific.

Circle No. 114 on Reader Service Card.

Ultra's new standards.

● Du Pont's Prep Type OD cartridges for the automated solid phase extraction of lipophilic components from aqueous samples are designed to be used with the Du Pont Prep automated sample processor. The Type OD cartridge partitions components between a moving liquid phase of buffered aqueous sample matrix, wash solvent, or eluting solvent and a solid stationary phase of resin bed. Both aqueous and organic solvents may be used to extract lipophilic analytes from aqueous solutions. Each cartridge comprises a cap, a 4 ml extraction column, a 6 ml effluent cup, and 4 ml recovery cup. Du Pont also provides a method development guide to aid extraction of lipophilic analytes.

Circle No. 115 on Reader Service Card.

The smallest CO₂ electrode?

● The MI-720 micro-carbon dioxide electrode is claimed to be the smallest commercially available CO₂ electrode capable of measuring CO₂ in small volumes and droplets. Its tip with membrane attached is 3mm in diameter and its total length is 6.2cm. Its useful concentration range is 10⁻² to 10⁻⁴ (440 to 4.4 p.p.m.) CO₂. The MI-720 is one of a range of "small volume" electrodes from Contact Microelectronics, Inc. of Londonderry, New Hampshire.

Circle No. 116 on Reader Service Card.

From Houston Instruments/Bausch & Lomb, the 4500 MicroScribe.

● The Series 4500 MicroScribe strip chart recorder from Houston Instruments is one of a new generation of recorders using microprocessor control and touch-panel switching. The recorder's centralized liquid crystal display provides constant information about operating parameters as well as self-test messages such as 'paper out' or voltage 'out of range'. Charts from the Series 4500 span a full 20 cm, at speeds ranging from 1 cm per hour to 60 cm per minute. Linearity is within 1% full scale; response is 0.25 seconds for full-scale.

AUTHORS WANTED BY N.Y. PUBLISHER

A well-known New York subsidy book publisher is searching for manuscripts worthy of publication. Fiction, non-fiction, poetry, juveniles, travel, scientific, specialized and even controversial subjects will be considered. If you have a book-length manuscript ready for publication (or are still working on it), and would like more information and a free booklet, please write:

Vantage Press, Dept. D-69
516 W. 34th St., New York, N.Y. 10001

Circle No. 34 on Reader Service Card.

COMMON SENSE AND HUMOUR IN PHYSICS

**2+2=2
O.K.?**

Leonard Parish

This amateur Scientist takes an irreverent but well argued view of various scientific theories, especially that of Einstein's Relativity. A book to make you think, question and smile.

Hardback, 222pp. ISBN 0 904378 24 1 £9.75

Also by the same author

The Logical Flaws of Einstein's Relativity
Hardback, 180pp. ISBN 0 904378 03 9 £6.50

The Theory of Cosmic Aberration
Softback, 52pp. ISBN 0 904378 11 X £3.50

Obtainable from booksellers or from the Publishers:
Courtney Publications, 95-115 Windmill Road, Luton.

Circle No. 06 on Reader Service Card.

Kimble's disposable glass centrifuge tubes.

● Kimble disposable borosilicate glass centrifuge tubes combine the advantages of glass and the economy of disposables. Borosilicate glass gives superior chemical durability over plastic, even with pH sensitive solutions and organic solvents. These tubes have standard GPI threads and are available in 5ml, 10ml, and 15ml sizes. Each size fits standard centrifuge cups and can withstand a centrifuge speed of 3,000RCF.

Circle No. 118 on Reader Service Card.

● A new restriction enzyme, *Asp718*, is now available exclusively from Boehringer Mannheim Biochemicals. This enzyme recognizes the same sequence as *KpnI*, GGATACC, but produces 5' protruding cohesive ends, instead of the 3' ends produced by *KpnI*. This enzyme has one recognition site in simian virus 40 DNA, but no sites in pBR322 or 328 DNA.

Circle No. 119 on Reader Service Card.

● Spectra-Physics' new liquid chromatography sampling system, the SP8780XR automatic sampler, is a stand-alone module which automates any modular liquid chromatography system, while also providing fully integrated operation with other Spectra-Physics LC modules. Control and communication are provided via the company's local area network, LABNET, RS-232-C, and contact closure circuits. A novel feature of the SP8780XR is the ability to use bar code labels on each individual sample vial. The bar codes provide each vial with a unique identification to aid in sample tracking and eliminate errors in tray loading. The code also carries analysis file information for each vial, thereby automating instrument setup in LABNET systems.

Circle No. 120 on Reader Service Card.

● A new bench-top liquid scintillation counter from Beckman, the LS1801, is a three-channel system featuring a rack sample changer that will accommodate either standard vials (336 samples) or miniature vials (648 samples). Beckman's Versa-Rack sample changer allows both types of vial to be used in the same instrument without the need for adapters. An exclusive feature on Beckman counters is the Horrocks number method of quench monitoring. One quench curve generated using *H* number will provide accurate results, regardless of the volume of sample, type or vial or choice of cocktail. The LS 1801 can carry out microvolume counting with a sample/cocktail volume as low as 200 μ l, thus cutting consumable costs.

Circle No. 121 on Reader Service Card.

● Intended for use with the Flow Titertek 8- or 12-nozzle pipettors, the new Ejector Bars produced by Robbins Scientific guarantee ejection of every tip, every time. Made of durable, solid aluminium, they can be attached quickly and easily to Titertek pipettors. They replace existing bars with no pipettor modification required.

Circle No. 122 on Reader Service Card.

● Normal- and reverse-phase silica media for liquid chromatography have been added to the Amicon Corporation range. Matrex silica chromatographic media are available in a wide range of particle sizes, with pore sizes ranging from 60 to 250 Å. All may be ordered with C18 or C8 functionality for reverse-phase applications. Equivalent capacity and selectivity factors for all particle sizes are especially valuable for direct scale-up to large preparative applications, avoiding the necessity of method redevelopment.

Circle No. 123 on Reader Service Card.

Spartan filters for use with syringes.

● The Schleicher & Schuell Spartan filtration system, a series of three syringe filters, allows fast, convenient filtration of small volumes when preparing individual HPLC samples. The pre-assembled, disposable syringe filters minimize sample hold-up volumes, save time, and eliminate cross-contamination. The chemically resistant microfilters effectively remove sample and solvent contaminants which can cause erroneous HPLC readings or damage columns, valves or pumps. The filters are designed with a Luer-lock fitting to securely fasten the unit onto the syringe. The Spartan-3 all-nylon filter handles volumes of less than 1 ml with a design that ensures extremely high recovery rates. The S&S nylon-66 membrane of 3-mm diameter is secured in a nylon housing. Suitable for aqueous and most organic filtrations, Spartan-3 can be specified in pore sizes of 0.2, 0.45 or 5.0 μ m. Spartan-25, designed for volumes of 1 to 50 ml, offers the "universal" filtration capability of a nylon-66 membrane in a polypropylene housing. The 25-mm-diameter microfilter completely filters aqueous and most organic samples. Pore sizes are 0.2, 0.45 or 5.0 μ m. Spartan-T is designed for filtering acids or harsh organic solvents that are not compatible with nylon. The chemically resistant, hydrophobic filter unit handles volumes up to 50 ml. Its 0.45- μ m Teflon membrane of 30-mm diameter is housed in a rugged polypropylene holder.

Circle No. 124 on Reader Service Card.

● The 1984 Product Reference Guide from Pharmacia P-L Biochemicals, which lists products for biochemistry and molecular biology, is now available. The guide is divided into sections based on product categories which include: Enzymes, Restriction nucleases, Nucleic acids for molecular biology, Polynucleotides, Nucleotides, Coenzymes, Affinity chromatography, Antibiotics, Buffers, Carbohydrates, Immunologicals, Lectins, Lipids and Phorbol esters.

Circle No. 125 on Reader Service Card.

● New from BBL is an inorganic iodine stain product to improve Gram staining. The new iodine offers an alternative to breakage of glass ampoules to prepare a working iodine solution. The BBL Gram's iodine with concentrate is packaged in component sets containing four 250-ml polypropylene bottles of diluent with four 25-ml bottles of iodine concentrate. As with other BBL Gram stain reagents, the new product features a flip-top cap, compact tray/work station and stain resistant labels. The two bottles mix readily to prepare the working iodine solution. The current BBL stabilized PVP iodine products (in kits, sets or gallon form) are still available to microbiologists who prefer the elimination of the working solution preparation step and a longer stability.

Circle No. 126 on Reader Service Card.

● Oligonucleotide hybridization probes of extremely high specific activity have been used successfully to detect many different genes by hybridization analysis. A new technical information bulletin (Bulletin T-1588) from Beckman Instruments, Inc. shows how to use the Model 170 radioisotope detector to automate the sample handling of the preparation of labelled oligonucleotides to minimize radiation exposure. The detector can be used for desalting labelled oligonucleotides, minimizing the exposure to large amounts of radiation and providing analog records of the run in addition to integration data that enables easy calculation of the specific activity.

Circle No. 127 on Reader Service Card.

● A new addition to Vector Laboratories biotin/avidin system line of products is the amplifying agent biotinylated anti-avidin D. This molecule is capable of binding to avidin D via its biotin residues as well as through conventional antibody-antigen interactions. The potential for multiple-site binding appears to provide this antibody with unusual characteristics. When used in conjunction with fluorescent or enzyme-conjugated avidin D, a large amplification of the primary signal can be achieved. This reagent can be used with biotinylated DNA hybridization probes, hormones, toxins, antibodies or lectins to enhance the desired signal.

Circle No. 128 on Reader Service Card.

These notes are based on information provided by the manufacturers. For further details circle the appropriate numbers on the Reader Service Card bound inside the journal.

Awards

Twenty-nine research fellowships have been awarded under the European Science Exchange Programme as follows: **Ms Victoria J. Allan**, Department of Biology, University of York, to spend one year from February 1985 at the European Molecular Biology Laboratory, Heidelberg, Federal Republic of Germany; **Mr Ilesh Bidd**, School of Chemistry, University of Bristol, to spend one year from January 1985 at the Institut de Chimie, Université Louis Pasteur de Strasbourg, France; **Mr Alexander W. Blayney**, University Hospital of Wales, Cardiff, to spend one year from January 1985 at the department of otolaryngology, University of Bordeaux, France; **Mr David H. Burgess**, School of Mathematical Sciences, Queen Mary College, London, to spend one year from January 1985 at the section d'astrophysique, Observatoire de Paris, Meudon, France; **Mr I. Colin G. Campbell**, Department of Mathematics, King's College, London, to spend one year from January 1985 at the Institute of Theoretical Physics, University of Stockholm, Sweden; **Mr David B. Carpenter**, Department of Physics, University of Edinburgh, to spend nine months from January 1985 at the Deutsches Elektronen-Synchrotron, Hamburg, Federal Republic of Germany; **Mr Christopher Carr**, Department of Inorganic Chemistry, University of Bristol, to spend one year from January 1985 at the Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden; **Mr Christopher L. Clayton**, Department of Applied Biology, University of Wales Institute of Science and Technology (UWIST), Cardiff, to spend one year from January 1985 at the Department of Medical Biochemistry, University of Geneva, Switzerland; **Miss Margaret E. Collins**, Department of Botany and Microbiology, University College, Cardiff, to spend one year from January 1985 at the Institut de Génétique Moléculaire, Centre National de la Recherche Scientifique, Gif-sur-Yvette, France; **Mr George M. Coupland**, Department of Molecular Biology, University of Edinburgh to spend one year from January 1985 at the Institut für Genetik, University of Cologne, Federal Republic of Germany; **Mr Irwin B. Davidson**, MRC Institute of Virology, University of Glasgow, to spend one year from March 1985 at the Laboratoire de Génétique moléculaire des Eucaryotes, Centre National de la Recherche Scientifique, Strasbourg, France; **Mr Christopher S. Durbin**, School of Geography, University of Manchester, to spend one year from July or September 1985 at the Laboratoire de Géomorphologie, Université Libre de Bruxelles, Belgium; **Mr John L. Edwards**, School of Chemistry, University of Bristol, to spend one year from January 1985 at the

Collège de France, Paris, Francis; **Dr Catherine W. Gill**, Marine Science Laboratories, University College of North Wales, Menai Bridge, to spend one year from October 1984 at the Station Marine de Roscoff, France; **Mr David R. Greaves**, Biophysics Department, King's College, London, to spend one year from January 1985 at the Netherlands Cancer Institute, Amsterdam, the Netherlands; **Miss Kim E. Hammond**, School of Biological Sciences, University of East Anglia, Norwich, to spend one year from January 1985 at the department of phytopathology, Agricultural University, Wageningen, the Netherlands; **Dr Barbara J. Hart**, Department of Zoology, University of Glasgow, to spend one year from September 1984 at the Institut Royal des Sciences Naturelles de Belgique, Brussels; **Miss Elaine J. Hughson**, Department of Haematology, Royal Hallamshire Hospital, Sheffield, to spend one year from October 1984 at the European Molecular Biology Laboratory, Heidelberg, Federal Republic of Germany; **Mr Benjamin P. Jeffries**, Mathematical Institute, University of Oxford, to spend one year from January 1985 at the Max Planck Institute for Physics and Astrophysics, Munich, Federal Republic of Germany; **Dr Deborah J. Jones**, Department of Chemistry, University of Southampton, to spend one year from 1 October 1984 at the Laboratoire des Acides Minéraux, Université des Sciences et Technique du Languedoc, Montpellier, France; **Dr Peter J. McDonald**, Department of Physics, University of Nottingham, to spend one year from January 1985 at the Service de Physique du Solide et de Résonance Magnétique, Saclay, France; **Dr Janice G. Mather**, Department of Zoology, University of Manchester, to spend one year from October 1984 at the Institute of Zoology and Zoophysiology, University of Aarhus, Denmark; **Mr Ronald A. Milligan**, Department of Structural Biology, Stanford University School of Medicine, California, USA, to spend one year from April 1985 at the European Molecular Biology Laboratory, Heidelberg, Federal Republic of Germany; **Dr Jonathan Mitchley**, Botany School, University of Cambridge, to spend one year from January 1985 at the Department of Plant Ecology, University of Utrecht, the Netherlands; **Mr Michael J. Morris**, School of Chemistry, University of Bristol, to spend one year from January 1985 at the Institut de Chimie, Université Louis Pasteur, Strasbourg, France; **Mr Mark A. Riley**, Department of Physics, University of Liverpool, to spend one year from October 1984 at the Niels Bohr Institute, University of Copenhagen, Denmark; **Mr Andrew Robinson**, Department of Astronomy, University of Manchester, to spend one year from January 1985 at the European Southern Observatory, Garching bei München, Federal Republic

of Germany; **Mr Robin G. Stuart**, Clarendon Laboratory, University of Oxford, to spend one year from May 1985 at the theory division, CERN, Geneva, Switzerland; **Dr Simon G. Webster**, School of Animal Biology, University College of North Wales, Bangor, to spend one year from October 1984 at the Institut für Zoophysiology, Rheinische Friedrich-Wilhelms-Universität, Bonn, Federal Republic of Germany.

The Royal Society of Chemistry has announced a cycle of new awards for British and Commonwealth citizens sponsored by various industrial companies; separate prizes are available to scientists working in the fields of: Analytical Separation Methods; Chemical Analysis and Instrumentation; Chemical Education; Health Safety or Environmental Chemistry; Hydrocarbon Oxidation Chemistry; Main Group Element Chemistry; Natural Product Chemistry; Organic Reaction Mechanisms; Solids and Materials Processing; Spectroscopy; Structural Chemistry; and Thermodynamics. Awards will be available for a different range of subjects in subsequent years. Further details from Mrs Y.A. Fish, The Royal Society of Chemistry, Burlington House, London W1V 0BN, UK.

The first in a series of scientific research funding awards, worth over £380,000 a year has been announced by the Wellcome Trust, Britain's largest medical charity, in association with the Royal Australasian College of Physicians. The first two Australian Wellcome Senior Research Fellows will be **Dr. David Healy** of the Prince Henry's Hospital, Melbourne, who will work on hormone activity in pregnancy during his studies on endocrinology in obstetrics and gynaecology, and **Dr Keryn Williams** who will be investigating the problems of rejection in corneal transplants at Flinders University, Adelaide.

To celebrate one hundred years of publication of Baillière's Clinical Pharmacology, **Baillière Tindall** is sponsoring an essay competition for medical and pharmacy undergraduates. There is a first prize of \$1,000 and two second prizes of \$500; further information is available from The Editorial Director, Baillière Tindall, 1 St Anne's Road, Eastbourne, East Sussex BN21 3UN, UK. The Royal Swedish Academy of Sciences has awarded the **Crafoord Prize** for ecological research to **Professor Danial H. Janzen**, a Professor at the University of Pennsylvania, USA, for his studies on co-evolution.

A major European Conservation Award scheme has been announced by the **Ford Motor Company**, operating in eight European countries: Austria, Holland, Belgium, Italy, Spain, Switzerland, France, and the United Kingdom. Total funds exceed \$100,000 and projects can be submitted in up to six different categories

including rural, urban and heritage conservation. Further information can be obtained from The Conservation Foundation, 11a West Halkin Street, London, SW1X 8JL, UK.

The International Agency for Research on Cancer is inviting applications for its Training Fellowships and a Visiting Scientist Award for 1985/86. Further details obtainable from the Chairman of the Fellowships Selection Committee, International Agency for Research on Cancer, 150 Courts Albert-Thomas, 69372 Lyon Cedex 08, France.

Pool Bioanalysis Italiana, is inviting entries of scientific papers on environmental microbiology in their first international competition; the prize is one week's holiday in Rome. Any paper in which SAS, SAS Compact or MTM-3 air samplers have been used is acceptable. For further details write to "P.B.I.", 1st International Competition, Via Novara 89, 20153 Milano, Italy.

Nominations are now open for the 1985 **Lita Annenberg Hazen Awards for Excellence in Clinical Research**, the purpose of which is to encourage increased participation in clinical research by physicians. Prizes amounting to \$100,000 are available and further details can be obtained from James F. Glenn, M.D., President, The Mount Sinai Medical Centre, Chairman, The Lita Annenberg Hazen Awards Program, 1 Gustave L. Levy Place, New York, New York 10029, USA.

The **Smithsonian Institution** award post-doctoral, predoctoral and graduate research fellowships in the fields of *inter alia*, the History of Science and Technology, Earth Sciences, Anthropology, and Biological Sciences. For details and application forms contact the Office of Fellowships and Grants, Desk J, 3300 L'Enfant Plaza, Smithsonian Institution, Washington, D.C. 20560, USA.

Appointments

Dr Denver Hall has been appointed to the Unilever Chair in Colloid and Surface Chemistry at the University of Salford.

Professor Barry R. Jennings of the University of Brunel has been appointed as the new Professor of Physics at the University of Reading.

Meetings

14 November, **Meeting on the Use of Physical and Analytical Techniques in Drugs Research**, London (Conference Secretariat, Society of Chemical Industry, 14 Belgrave Square, London SW1X 8PS, UK).

22-23 November, **Clonal Evolution of Tumours**, British Association for Cancer Research/Royal Society of Medicine Joint Winter Meeting, London (Barbara Cavilla,

BACR, c/o Institute of Biology, 20 Queensberry Place, London SW7 2DZ, UK).

29 November, **One Day Symposium on Food Production and Our Rural Environment — The Way Ahead**, London (Centre for Agricultural Strategy, University of Reading, 1 Early Gate, Reading RG6 2AT, UK).

4-6 December, **8th International Online Information Meeting**, London (Learned Information (Europe) Ltd, Besselsleigh Road, Abingdon, Oxford OX13 6LG, UK).

25 February-1 March, **36th Pittsburgh Conference and Exposition on Analytical Chemistry and Applied Spectroscopy**, New Orleans, USA (Mr David R. Weill III, 437 Donald Road, Pittsburgh, Pennsylvania 15235, USA).

25 February-1 March, **International Conference on Climatic, Biotic and Human Interactions in the Humid Tropics**, Sao Jose dos Campos, Brazil (Mr Walter Shearer, Senior Programme Officer, Development Studies Division, The United Nations University, Toho Seimei Building, 15-1, Shibuya 2-chome, Shibuya-ku, Tokyo 150, Japan).

25-28 March, **2nd Conference of the International Association for Breast Cancer Research**, London (Dr Marvin Rich, AMC, Cancer Research Center, 6401 West Colfax Avenue, Lakewood, Colorado 80214, USA).

1-4 April, **3rd International Meeting on Low Temperature Microscopy and Biological Analysis** Cambridge, UK (The Administrator, Royal Microscopical Society, 37/38 St. Clements, Oxford OX4 1AJ, UK).

3-4 April, **21st Annual Meeting of the National Council on Radiation Protection and Measurements**, Washington D.C., USA (Mr Roger Ney, NRC, 7910 Woodmont Avenue, Suite 1016, Bethesda, Maryland 20814, USA).

10-12 April, **International Symposium on Chemistry and Physics of Baking: Materials, Processes and Products**, Sutton Bonington, Leicestershire, UK (Mr J.M.V. Blanshard, Department of Applied Biochemistry and Food Science, The University of Nottingham, School of Agriculture, Sutton Bonington, Loughborough, LE12 5RD, UK).

16-18 April, **International Symposium on the Impact of Biotechnology on Diagnostics**, Rome, Italy (Organizing Secretariat, Fondazione Giovanni Lorenzi, Via Montenapoleone 23, Milan, Italy).

16-18 April, **Conference on Advanced Computational Techniques for Information Retrieval**, Oxford, UK (The Association for Information Management, 3 Belgrave Square, London SW1X 8PL, UK).

23-24 April, **Meeting on Material Properties and Stress Analysis in Biomechanics**, Brunel University, UK (The Institute of Physics, Meetings Office, 47 Belgrave Square, London SW1 8QX, UK).

27 April-2 May, **Congress on Laboratory Medicine**, Hamburg, FRG (Dr O. Fenner, Organizing Committee, Kongress für Laboratoriumsmedizin, Hamburg Messe und Congress GMBH, Ausstellungsabteilung, Postfach 30 24 80, D-2000 Hamburg 36, FRG).

28 April-1 May, **International Conference on Arctic Water Pollution Research: Applications of Science and Technology**, Yellowknife, Northwest Territories, Canada (Conference Services Office, National Research Council of Canada, Montreal Road Laboratories, Ottawa K1A 0R6, Canada).

28 April-4 May, **21st EUCHEM Conference on Stereochemistry**, Bürgenstock, Switzerland (Professor M. Julia, Laboratoire de Chimie, E.N.S., 24 rue l'homond, 75231 Paris Cedex-05, France).

29 April-2 May, **23rd International Magnetics Conference**, St. Paul, Minnesota, USA (Mr J.A. Nyenhuis, School of Electrical Engineering, Purdue University, West Lafayette, Indiana 47907, USA).

30 April-3 May, **Conference on Computer Aided Production Management**, Wembley, Middlesex, UK (The Manager — Conferences and Exhibitions, The Institution of Production Engineers, Rochester House, 66 Little Ealing Lane, London W5 4XX, UK).

7 May, **37th International Symposium on Crop Protection**, Ghent, Belgium (The Secretary, Faculteit Van de Landbouwwetenschappen, Rijksuniversiteit, Coupure Links, B-9000 Gent, Belgium).

9-10 May, **International Symposium on Thyroid Function Tests**, Ile de Bendor, France (The Secretariat, Laboratoire des Hormones Proteiques, Faculté de Médecine, F-13385 Marseille Cedex 5, France).

21-23 May, **Biotech 85 Europe**, Geneva, Switzerland (Online Conferences Ltd, Pinner Green House, Pinner, Middlesex, HA5 2AE, UK).

21-23 May, **7th Annual Symposium on Safeguards and Nuclear Material Management** Liège, Belgium (Mr L. Stanchi, CEE-JRC, I-21020 Ispra Varese, Italy).

22-24 May, **International Congress on Tissue Integration in Oral and Maxillo-Facial Reconstruction**, Brussels, Belgium (Dr D. van Steenberghe, Faculty of Medicine, Catholic University Leuven, Kapucijnenvoer 7, B-3000 Leuven, Belgium).

3-7 June, **International Symposium on Vaccines and Vaccinations**, Paris, France (Secretariat, Symposium on Vaccine and Vaccinations 1985, Institut Pasteur, 28 Rue du Docteur Roux — 75724 Paris Cedex 15, France).

4-6 June, **International Seminar on Electronics and Traffic on Major Roads**, Paris, France (Secretariat of the Seminar on Electronics and Traffic, European Conference of Ministers of Transport, 19 rue de Franqueville, 75775 Paris Cedex 16, France).

What will happen to UNESCO?

The British Government seems about to follow the United States into resignation from UNESCO. That will not be the end of the world (or even of UNESCO).

THE next few weeks will decide whether the UN Educational, Scientific and Cultural Organization (UNESCO) will survive in its present shape into the 1990s. And the outlook is far from bright. There now seems very little chance that the United States will go back on its decision of a year ago to pull out six weeks from now. The State Department's demand that the UNESCO administration should mend its ways has been partly met, but not sufficiently to persuade a president temperamentally biased towards withdrawal to change his mind. And there seems to be a strong constituency, among UNESCO's users in the United States, that last year's decision should be unscrambled (see p.300).

UNESCO's problem of managing without a quarter of its budget has now been further complicated by the chance that the United Kingdom will also, in the next few weeks, give notice of withdrawal. Such a decision, on the cards since the stern letter to UNESCO from the British government earlier in the year, has been made more likely by the tightness of the budget on which the Foreign and Commonwealth Office will have to live in the next three years. Even UNESCO's supporters in Britain, those who have held that £5 million a year is a small price to pay for continued membership of an organization from which withdrawal is bound to give widespread offence, will think differently when they recognize that the UNESCO subscription can be paid only at the expense of other useful activities — those of the British Council (the United Kingdom's own UNESCO), of the overseas broadcasts of the British Broadcasting Corporation or of direct foreign aid (for example to Ethiopia). So it is likely that the British government, anxious to clear its collective desk before the end of the year, will write a letter giving notice of withdrawal, put it in the mail and hope that the fuss will be dissipated during the coming holidays.

But what fuss? The obvious risks of withdrawal from UNESCO are political. To pull out of one UN organization is to put membership of all others in doubt, inviting the complaint that loyalty to international causes has been undermined. Because UNESCO has become widely regarded by the governments of developing countries as one of the chief vehicles for the transfer of the skills of advanced societies to those that lack them, those that withdraw will run the further risk of being thought indifferent to the cause of development. And because the row within UNESCO has been closely linked with personal criticism of the present director general, Mr Amadou-Mahtar M'Bow, enthusiastically the choice of the non-aligned countries on his appointment ten years ago, pulling out is bound to seem a slap in the face to those who voted for him in the first place.

Justification

The United States government is better able to meet these complaints head on than is the British; it can always point to the scale of its financial contributions to international organizations

of all kinds, the International Monetary Fund and the World Bank as well as the United Nations system. The British government has less to boast about, and is politically involved with many of UNESCO's fondest friends through the machinery of the British Commonwealth. If Britain does in the end withdraw, it had better pay close attention to the way in which its decision is justified.

Many of the complaints against UNESCO in the past several years are beside the point. Both the US and British governments say that UNESCO, with its remit to consider matters educational, scientific and cultural, should not be caught up in the political arguments that have dominated its general assemblies in recent years. But that is to ask too much. An organization whose terms of reference give it a proper interest in the care of the cultural heritage (and which has done valuable work in safeguarding the monuments along the Nile) cannot, for example, avoid also giving Greece an opportunity for attacking the British government because the Elgin marbles, which once adorned the Parthenon, are still on show in the British Museum. Similarly, it has from the start been inevitable that UNESCO should have been a battleground for conflicting interests over issues such as the control of copyright on publications (and the 1971 Paris amendment to the Berne Convention on copyright is both a feather in UNESCO's cap and a considerable victory for developing countries within UNESCO).

Given UNESCO's membership and constitution, such issues have been unavoidable from the start. Even Mr M'Bow's "new information order", a set of proposals whose immediate effects on the international news gathering agencies would have been disastrous, and which would also have legitimized the ambitions of governments to control what is said about them, was a proper question for UNESCO to consider. The complaint against UNESCO, and its management in particular, is that it seems not to have wished to lift a finger to avoid irreconcilable conflicts on these issues. Indeed, it has often seemed to relish them.

Blame

For this state of affairs, the developing countries must shoulder a substantial part of the blame. UNESCO is not by its constitution a supranational authority whose decisions are binding on its members, but rather a forum in which countries with something that others want may be persuaded to offer it. This is what happened with the revision of copyright protection, an international convention in whose negotiation UNESCO acted as a midwife, by which governments of developing countries were given limited rights to use educational materials if the original publishers are unable or unwilling to make them available. The difficulty that has arisen in the past few years is that the principle of one government, one vote, has gone to the heads of a majority of the membership. Arguments about issues such as the new information order are one thing (and should be tolerable), but proposals to spend a substantial part of communal funds supplied chiefly by those opposed to the proposal are another. One of the changes at UNESCO for which the United States has been pushing in the past year is the replacement of the present voting procedure by one in which those who pay the most have the most influence, but that would have been a cosmetic device for burying conflict, not for creating the atmosphere of consensus without

Science in the Soviet Union

THE special issue of *Nature* surveying science in the Soviet Union has been delayed until next month. □

which any communal fund must be misspent.

But why has the management allowed things to come to such a pass? That is a question that may always be fairly asked when a voluntary organization is in danger of being torn apart by internal conflicts. The usual answer is that the management has failed to spot trouble coming, and to head it off. That complaint unquestionably applies to UNESCO's management in the past few years. Mr M'Bow has been most often criticized, during UNESCO's troubled two years, for his tolerance of inefficiency, for his dictatorial ways with UNESCO's staff, for nepotism and because of his undoubted vanity. But the failing that matters is that he has not been able, or has not chosen, to function as the diplomat an organization such as UNESCO needs. Whatever members depart from UNESCO in the next few weeks, there is the strongest possible reason why Mr M'Bow should also quit — or be asked to go. UNESCO will be a substantial organization even if Britain follows the United States (and is followed by other members) into the cold. Especially with a shrunken budget, there is the strongest reason why UNESCO should be managed well.

Inevitably, it goes against the grain for governments wedded to the doctrine that it is injudicious (to say the least) to attack people and not policies to tell Mr M'Bow outright that he is an encumbrance to the organization he purports to head. Even so, it is mystifying that Mr George Shultz, when giving notice a year ago of the United States' intentions to withdraw, should have gone out of his way to emphasize that Mr M'Bow's misfortune is that he happens to have led UNESCO from a state of inconspicuous mediocrity to one of conspicuous failure. He would have been better served if the member governments now bent on withdrawing had told him sooner, and to his face, what they were always eager to tell others privately. He may now fairly complain that he was set up. But he has been a failure nevertheless.

By now, the principles on which reform should be sought are plain. Since it began, UNESCO has been wrongly organized for what it is now hoping to accomplish, the spending of a relatively modest \$200 million a year on good works scattered about the surface of the Earth. In effect, it is a modestly-sized charitable foundation whose terms of reference are international, but it is organized not for spending money efficiently but as if it were the kernel of an evolving academy of all the talents. The result is that the members of its staff are never sure whether they have been appointed in their capacity as scholars or as people who can channel funds to others who will be productive. And there are too many of them, by any set of job-descriptions, perhaps by an order of magnitude. It is laughably outrageous that UNESCO should spend two-thirds of its income on itself. When the present alarm about withdrawal, intended or merely threatened, is over, the remaining members should set about putting things to rights. The French government should be well placed to take the initiative.

Determination

What needs to be done is simply told. Inefficiency apart, UNESCO differs from other organizations. Ideally, its role should be to sponsor international intellectual projects that others have not attempted, being prepared to see many of these fail but resolute in its determination that those that succeed should be launched independently, with other people's funds, once their success is apparent. Instead, UNESCO has more often waited for other people's band-wagons to pass, seeking a small share in their sponsorship but a larger share of the credit. This, for example has been UNESCO's stance during the past quarter of a century in respect of the improvement of science teaching in secondary schools, where great opportunities have been missed for translating internationally programmes that have functioned well in member states. By contrast, UNESCO has embraced with too much enthusiasm schemes for teaching what is loosely called "peace" to unsuspecting teenagers throughout the world in circumstances when the most sophisticated educational systems are unable to provide models on which to practise what is being preached.

The conventional assumption is that none of these criticisms applies to UNESCO's scientific work, but even that claim is

shaky. It is, however, true that UNESCO is at present the conduit for continuing support for some important institutions, the International Council of Scientific Unions (ICSU) and the International Centre for Theoretical Physics (at Trieste), originally supported by the International Atomic Energy Agency. There is the strongest case why such institutions should not collapse, and why members thinking of withdrawing from UNESCO should ensure that their contributions to these central organizations should continue. UNESCO has also become the umbrella for a number of important coordinating research committees, the best known and most useful in oceanography. Thus the organization provides house-room and a secretariat for the International Oceanographic Commission, and also gathers oceanographic data collected by merchant vessels on routine voyages — tasks not at present done by other means. But UNESCO happens to be responsible only by accident, because it was the first to take on these tasks. As things have turned out, it would be more appropriate that such jobs should be done by ICSU or one of its member councils — and that the practical task of data-storage should be turned over to suitable laboratories working to contracts.

What might have been UNESCO's pride and joy in the past few years, however, the Man and Biosphere Programme (which is really an umbrella for a host of coordinated ecological projects scattered over the surface of the Earth, separately financed by national governments), is one to which the management in Paris has devoted much less enthusiasm than the case demands. But there is enough merit in UNESCO's scientific programme for the price of withdrawal from the organization to be an undertaking that the deserving parts of the programme should not be harmed.

Earlier this year, a committee of the US National Academy of Sciences under Walter A. Rosenblith of Massachusetts Institute of Technology made just this point to the State Department. Will the British government be prepared to follow suit? Its first reaction will be to say that if there is a chance of saving £5 million a year, it would prefer to keep the lot for other deserving causes. But this would be unacceptable, at least if worthwhile international institutions are to be endangered. Another unavoidable question is that of whether ICSU will be able to shoulder the extra burdens likely to be thrust on it even if the United States is the only member to pull out of UNESCO. The answer is that, at present, ICSU as such is not equipped to do much more than organize the committees necessary to ensure its continuing existence, but that situation need not persist. Indeed, there is a strong and quite separate case why, in the interests of the international community, ICSU should now be strengthened, and equipped with the resources necessary for it to play a stronger executive role in international science. But there is an obvious danger in supposing that ICSU might become a partial substitute for UNESCO — that ICSU might in the process itself be damaged, and that in any case there is no escaping some of the political difficulties that have made UNESCO uncomfortable in the past few years.

Reorganization

How, in these circumstances, should the British government decide? The question is not black and white. Pulling out regardless of the consequences would be foolish (and is unlikely). Pulling out without being prepared to pick up the pieces would similarly be wrong. Giving notice of withdrawal on the vague understanding that the decision might be reversed if UNESCO mends its ways would be fruitless, as the experience of the United States in the past year has shown. The best course is to couple a declaration of an intention to withdraw (not necessarily a year from now) with a prospectus describing how UNESCO might be organized efficiently, and how its reduced budget might nevertheless be spent effectively. The trouble, in the past year's bickering, is that it has concentrated on attempts to reform a well-intentioned organization absurdly ill-suited to its purposes by tinkering with the administration. What UNESCO needs is not to be told repeatedly why it is absurd, but to be helped to understand what it is for, and how it might function well. □

Fifth generation computers

Japan finds rivals treading uncomfortably close

Tokyo

JUDGING by the scale of Western governments' reactions to the fifth generation computer project, described by representatives to the project's international conference which ended in Tokyo last week, Japanese officials must be wondering if they would not have been better off keeping quiet about the whole subject.

Just three years ago, the project was launched in a storm of hyperbole that made it seem that Japan was about to seize world computer markets through a qualitative leap forward into a new world of super-intelligent computing systems. Now, Japan no longer looks the world leader as tough competing projects launched by the United Kingdom, the United States, France, Germany and the European Communities take off. Nor, despite earlier hopeful discussions between the United Kingdom and Japan, does there seem to be any longer a significant chance that cooperation will replace competition.

Strangely, the project that began it all, Professor Kazuhiro Fuchi's fifth generation computer project run from the Institute for New Generation Computing (ICOT), now looks academic and narrow, despite having been originally branded a "computing apocalypse" that would destroy Western nations' information technology industries. The explanation is Fuchi's continuing belief that the next phase of computer history will come from computers that use predicate logic to carry out inferences at high speed.

The language PROLOG, specially designed to handle such operations (see *Nature* 309, 198; 1984) has been taken as the project's starting point. With an inference mechanism at its core, the fifth generation project will try to use high speed mechanisms for retrieval from massive knowledge bases, permitting the computer to function as a highly intelligent "expert" system, while intelligent interfaces allow users to speak to their computers.

The intended results, very high speed inference and knowledge retrieval and intelligent man-machine interfaces, are what all the competing nations' projects aim at. But not everyone believes that predicate logic — and PROLOG — is the way to achieve them. As Daniel Bobrow of Xerox's Intelligent Systems Laboratory put it, "no single paradigm is appropriate to all problems. Just as there are many tools in a carpenter's tool box, there must be many in the programmer's kit." Fuchi sees many other approaches as being subsumed by logic programming (not to be confused with logical programming). If he

is right, his institute may well be way out in front in a couple of years; if not it could be left trying to "pry up nails with a screw-driver".

So far, anyway, ICOT has delivered on its promises. A working sequential inference machine was on display at the conference and will provide the essential "programming environment" (essentially equivalent to a laboratory bench and equipment) for further research. But from now on, the really hard problems begin — particularly that of parallel processing — where there are few clues as to which path or even which general philosophy will prove most profitable.

By contrast, Britain's Alvey Programme, although unashamedly inspired by ICOT's project, now looks quite catholic. It centres on four themes: software engineering, man-machine interfaces, intelligent knowledge-based systems and the development of very large scale integrated circuits, but admits of a variety of approaches. To counter the criticism best expressed by Robert Kowalski, one of PROLOG's inventors, that "it can be argued that it is harmful to support British research, because it is more likely to be exploited abroad than at home", all projects involve industrial participation and (almost) half industrial finance — even university-based projects have to find an industrial "uncle".

This in turn has led to an ICOT criticism of the Alvey project as "too incremental, too much aimed at short-term industrial application and lacking a basic research component" — exactly the complaints that have been flung at Japan's research for the past decade. And the industrial link has smashed hopes of cooperation between the United Kingdom and Japan. ICOT's project is 100 per cent supported by the government and ICOT will hold the patents.

With a budget of £350 million for the five years of the Alvey Programme, expenditure is running at double the rate of ICOT's project. But ICOT is only a tiny part of Japan's advanced computing effort: the telecommunications monopoly NTT's research laboratories have their own fifth generation project, and all of the large electronics manufacturers have artificial intelligence projects.

Only the United States, in total, is exceeding Japan's research efforts. Special projects launched there include the Defense Advanced Research Project Agency (DARPA)'s strategic computing programme (\$600 million over five years), the very high speed integrated circuit programme (\$100 million in 1984), other government programmes and new univer-

sity centres (\$100 million in 1984). There is also the private sector Microelectronics and Computer Technology Corporation and of course AT&T and IBM whose doings remain secret.

The West German response is more recent, stemming from the March 1984 government report on information technology which sets aside DM2,640 million over five years for information technology research. Collaboration between industry and the universities is again specially emphasized: key projects are on computer-aided design, new computer architectures and knowledge engineering.

France does not have a single grand plan, but has ambitions (see page 297). In 1983 the French initiated seven national projects, involving both industrial and public research laboratories, with themes broadly similar to those of the Alvey project. Now in preparation is a much longer-term set of fundamental research projects, centred on the Centre National de la Recherche Scientifique but also involving industry.

Finally, Esprit aims to overcome the European Communities' main weakness — fragmentation of research efforts — and rebuild the research base through "cooperation in precompetitive research and development". In 1984, 110 projects were being supported at 500 companies, institutes and universities, and expenditure of 200 million ECU approved.

All countries report that their biggest problem is finding trained staff — Alvey director Brian Oakley made in plain that anyone studying artificial intelligence will not be joining Britain's unemployed.

Alun Anderson

Apartheid telescoped

A PETITION signed by 156 UK astronomers has been handed to the Science and Engineering Research Council (SERC) calling for its links with the South African Astronomical Observatory (SAAO) to be cut, in the belief "that the continued funding (*sic*) of SAAO by SERC amounts to acquiescence in apartheid". SERC will not respond to the petition because, according to a spokeswoman, such decisions can be made by SERC only on the basis of scientific considerations.

SERC supports SAAO to the tune of about £250,000 a year together with travel and project grants to UK observers, who make considerable use of its facilities. Continuing use of the observatory is to be assessed next month as a matter of routine — though in the context of unusually tight financial constraints — during a "forward look" review by a sub-committee of SERC's Astronomy, Space and Radio Board. The controversy was last aired in 1982 when, as a result of a questionnaire circulated by SERC, it was reported that a majority of the community supported continued use of SAAO (see *Nature* 298, 698; 1982).

Philip Campbell

US research objectives

Keyworth's shopping list

Washington

MORE government support for research and training in biochemical engineering is urgently needed if the United States is to lead commercialization of the new biology, according to advice given by an expert panel to the White House Office of Science and Technology Policy (OSTP).

The panel, convened by the Committee on Science, Engineering and Public Policy (COSEPUP), says the United States lags in basic chemical engineering expertise and that if the position is not corrected, "the Japanese and the Europeans will certainly take the leading role".

The panel concludes that the government has a critical part to play in establishing US expertise in reactor design and purification methods and proposes a variety of grants and awards to be administered by federal agencies. The number of people graduating with higher degrees in biochemical engineering should be doubled or tripled from the present 60 per year.

The research briefing panel on chemical and process engineering for biotechnology is the most outspoken of 9 separate panels organized this year by COSEPUP. The briefings were given to OSTP officials, including director George Keyworth, during the autumn but published only last week.

COSEPUP briefings have over the past 3 years had a significant effect on OSTP policy; the proposed Engineering Research Centers, for example, stem directly from a COSEPUP initiative.

Dr Keyworth has this year taken a more active part in selecting subjects than previously. But while pleas for financial support for particular areas are taken seriously, according to officials, it is thought that some of the matters taken up by this year's briefing panels have already received special attention; in particular, the engineering research centres planned for some university engineering departments may go a long way towards meeting present needs.

A panel on computer architecture has urged immediate efforts to accelerate development of advanced software for the forthcoming generation of parallel processing computers: several indicators suggest that Japanese activities in this field exceed present US capability. And although the United States hopes that it can retain its lead in parallel processing hardware, the panel recommends that a body of specialists should be brought together to follow the Japanese technical literature to warn of any "technological surprises" coming from the much-vaunted fifth generation computer programme. The British Alvey programme of research and development should similarly be "watched closely". But the panel is ap-

parently unimpressed by the potential of the European Esprit programme.

Other areas where COSEPUP panels urge new federal initiatives include advanced polymer composites, laser-atomic interactions and relativistic plasma waves. Research on polymers is badly organized, according to one panel, and there should be a new emphasis on interdisciplinary training to bring together scientific skills needed for development of advanced organic polymers, possibly concentrated at special centres.

Another panel, on physics, argues the likely future importance of accelerators based on electric fields produced in plasma waves, high resolution spectroscopy using relativistic particle beams, and two-dimensional structures. In plasma physics and astrophysics, there is a need for improved computing facilities.

Australian pests

Legal framework for control

Canberra

THE Australian government's introduction of the Biological Control Bill 1984 is another milestone in the long struggle for supremacy over exotic pests. In the meat export trade, a large part of Australia's reputation as a reliable supplier of high-quality produce is the good health of its farm animals, with no outbreak of foot-and-mouth disease since 1872, rabies since 1867 or rinderpest since 1923.

By contrast, the difficulty in enforcing large-scale biological control of weeds and other crop pests in the Australian federal system is nowhere more clearly displayed than in the drawn-out conflict between beekeeper and landowner over the relative merits of the purple-flowered Mediterranean plant *Echium plantagineum* — known as Salvation Jane or Paterson's Curse, depending on one's point of view, and introduced into Australia more than a hundred years ago.

Since the turn of the century, various grazer groups in the sheep and cattle regions of southern Australia have had the vigorous exotic declared a noxious weed, claiming that it detracts from the fodder value of pasture land and produces pyrolyzidine alkaloids poisonous to cattle.

In 1974, all state departments of agriculture responded positively to an inquiry from the Division of Entomology of the Commonwealth Scientific and Industrial Research Organization (CSIRO) to prepare the release of exotic insect agents to control *Echium*. In 1978, supported by graziers from lower rainfall areas, the beekeepers protested that the proposed control programme should not proceed, proclaiming *Echium* the most important honeybee resource growing in south-east

In marked contrast with the recommendations on technology, however, panels reporting on opportunities in basic biology appear content with the existing federal role. An overview of the biology of oncogenes produced by a panel under the chairmanship of Dr Robert Weinberg of Massachusetts Institute of Technology, for example, concludes that further progress towards an understanding of cancer "will depend on continuing support of the basic biologic disciplines whose successes have proved so useful...".

A report on interactions of blood and blood vessels stresses the potential health benefits to be gained and advocates more research but demands no government action. The contrast has not been lost on OSTP. Parasitism, however, is identified as ripe for a major expansion, as molecular biology provides new techniques. Here, as in other areas, OSTP is told of a need to encourage more scientists to study the basic biology of the organisms involved.

Tim Beardsley

Australia and in some years the only spring crop available.

The controversy seesawed for two years until, in 1980, the *Echium* leaf mining moth *Dialectica scallariella* was released at three experimental sites in New South Wales. But later that year, the high court granted a restraining injunction on narrow grounds in favour of beekeeper and low-rainfall-zone grazier plaintiffs. CSIRO was required to halt importation of further European insects and to destroy those already released. Another agreement was reached in June 1982 to set up a tribunal to determine whether control of *Echium* should proceed at all, but this did not materialize.

Throughout the whole litigation period, which ended in June 1983 with CSIRO agreeing to a permanent injunction, the federal government had only a limited capacity to enact far-reaching biological control laws. Except for quarantine, most constitutional power in the area of exotic disease control, prevention and compensation resides with the states.

In August this year, however, the government introduced the Biological Control Bill which has passed in both houses and will soon become law, but only in the Australian Capital Territory. It provides for widespread advertising of proposed control programmes and a commission of inquiry and powers of review for individual cases. The bill in effect negates liability for the approved release of control organisms and is meant as a model for complementary legislation in the states. But because of the inability of either pest or bug to discern state boundaries, opponents of the bill will have to lobby successfully in only one state to disable the entire scheme.

Jeffrey Sellar

European computing

French bid to build centre

TOULOUSE in the south of France — a French centre for the aerospace industries, biotechnology and astrophysics — is making a serious play to become a major European focus for research and training in advanced scientific computation. The aim is to bring together computer scientists interested in new architectures (array or parallel processing, multi-instruction-stream computers and beyond), users and numerical analysts in a melting-pot that would be unique at least in Europe.

The Toulouse centre as at present planned would at least match a combination of the US National Aeronautics and Space Administration (NASA)'s Langley Institute of Computer Applications in Science and Engineering (ICASE) at Hampton, Virginia and the new NASA Research Institute for Advanced Computer Science (RIACS), which started just a few months ago at Ames, California.

This is not, however, a European "fifth generation" artificial intelligence (AI) experiment, although the Toulouse association for the promotion of the Centre Européen de Recherche et de Formation Avancé en Calcul Scientifique (CERFACS) wants to have available the most advanced computer possible, and is aiming to have its real impact in the 1990s.

The CERFACS objective is less ambitious than AI, and possibly more realistic. It stems from a growing feeling among "number crunchers" of all kinds that the new computer architectures and components require radically new techniques, and that interaction between users and computer designers is becoming essential. For example, says Professor Roger Hackney of the Department of Computer Science at the University of Reading, architectures designed to match particular problems can now be "a very cost-effective way of getting large computer power to the problem".

The best use of future and existing machines can be best learned and developed, it is felt, in a centre combining the disciplines of computer science (architectures), numerical analysis (algorithms) and applications specialisms. CERFACS would be such a centre. Nothing like it exists in Europe, Hackney claims. Moreover, NASA's ICASE and RIACS, while addressing all the relevant issues, concentrate architecture on the west coast and applications on the east.

Training and networking would also be "very important" at CERFACS. Visitors would come for several weeks or months, but then return to their home institutions, from which they would wish to keep in touch with CERFACS and use its computing power. So a satellite-based computer communications network is also proposed.

But will CERFACS get off the ground? The idea was the brainchild of Jean-Paul

Zahn, director of the Pic du Midi Observatory near Toulouse, but it has now been taken up with enormous enthusiasm by local industry and politicians such as the local mayor and European parliamentarian Henri Sabi.

However, the news from Brussels is not bright. Although the European Commission has set up a "study" of CERFACS, "we learned last week there's little prospect of Brussels cash in the next five years", said a CERFACS spokeswoman in Toulouse last week. "It just takes that long for the Commission to set up a programme."

So the hunt is on for support from the French government (said to be "very positive" to the idea), and from elsewhere. A European support committee has been established with members from the United

Kingdom, West Germany, the Netherlands, Spain, Greece, Denmark and Switzerland, which will report back early next year with the results of its approaches to government and other agencies.

CERFACS does have one guarantee: a purpose-built building. The Midi-Pyrénées regional government will pay for that. Internationally, Greece has already shown great interest, and smaller European nations may well prove more favourable than, say, Britain and West Germany, which already have large machines — even if they do not use them in the CERFACS manner.

France, however, is well behind Britain and West Germany in scientific computing power, so a conceivable outcome is that France will set up a joint arrangement for CERFACS between itself and the smaller nations of Europe. Whatever emerges from present soundings, a formal proposal to the French government will follow, probably in February. **Robert Walgate**

NIH

Academy recommends guide

Washington

A NATIONAL Academy of Sciences panel, after a year-long study, has suggested that the National Institutes of Health (NIH) might best defend themselves against the pressures of the "disease of the month club" by the time-honoured government strategy of injecting a new layer of bureaucracy into the organization. In recent years, a growing number of disease lobbies, acting through Congress, have pressed for the creation of new NIH institutes bearing the name of "their" disease. NIH has resisted these forces with varying success, but recently scored a victory when President Reagan vetoed a bill that would have established new National Institutes of Arthritis and of Nursing.

The academy recommendation is that there should be a new advisory body, to be called the Health Science Board, whose major purpose, it appears, would be to rechannel the public pressures that now find expression through Congress. The board would "communicate public perceptions of health research needs" to NIH and other Public Health Service agencies and would "assure the public that these needs are being . . . addressed".

Proposals for new NIH institutes would be subject to a formal review by the board, which would apply five criteria that would specifically exclude institutes whose major function is regulation, health services or other non-research activities. By these criteria, the National Institute for Occupational Safety and Health and the National Centers for Health Services Research and for Health Statistics — all of which, at some time, have been considered for incorporation into NIH — would be excluded.

The academy panel would not comment on specific proposals, such as that for an

arthritis institute, but advised that with NIH now having grown to 11 institutes, there should be a "presumption" against new additions. The panel's survey of NIH's organizational and budget history failed to produce evidence to substantiate the most often-heard justification for new institutes — that they boost support for the particular area of research and thus for NIH as a whole. (A spokesman for the Arthritis Foundation, for example, told the panel at a public hearing last year that by so visibly responding to such politically-popular health issues as arthritis, NIH could only gain. "We must see how we can take advantage of the system.")

By contrast, the panel concluded that new institutes add overhead costs, add to the administrative burden of an already overburdened NIH director (25 officials already report directly to him) and hinder scientific communication within NIH.

If the assurances of the Health Science Board are not enough to convince the public that their perceived health research needs are being met, NIH could avail itself of a "continuum" of options short of creating new institutes, the academy panel said. These options include "publicizing what scientific research has accomplished", holding conferences, naming special panels and creating new divisions or programmes within existing institutes.

A somewhat more tangible recommendation of the panel in helping NIH to respond to changing health research needs is for the creation of a contingency fund of 1 per cent of NIH's budget that the director could apply to health emergencies. At current spending, that one per cent equals about \$50 million, which may be more of a slush fund than Congress would be willing to create. **Stephen Budiansky**

Whaling

US and Japan agree to disagree

Tokyo

ANGRY criticism from press and politicians has greeted the Japanese government's decision to bow to US pressure and stop all sperm whaling by 1988. But there is some confusion over exactly what Japan has agreed to, with conflicting announcements in Washington and Tokyo, and protests from Greenpeace (the environmental pressure group) that Japan has got off far too lightly.

According to US negotiators, Japan has agreed to end by 1988 not just sperm whaling but all whaling. With this agreement, the United States hopes to avoid the bad feelings that would arise if, instead, it tried to use cuts in fishing quotas to force Japan

IWC ruling is not diminished.

Japan is, in any case, far more concerned about minke whales than sperm whales. At the same IWC 1984 meeting where the sperm whale quota was cut to zero, the Antarctic minke whale quota — upon which Japan's offshore whaling industry depends — was cut to 4,224 to be shared between Japan, the Soviet Union and Brazil. Both the Soviet Union and Brazil have formally objected to the quota, thus freeing themselves from obligation to abide by it. Japan has not so far objected because of its fear that US fishery cuts would follow. But immediately after the new agreement with the United States was announced, the agriculture, forestry and fisheries minister Moriyoshi Sato stated

that Japan will file an objection to the minke whale quota before the deadline of 6 January. The following year, the minke whale quota would automatically fall to zero as the total ban on whaling agreed by IWC in 1982 comes into effect.

It seems clear that the minke whale quota has been the subject of a US offer that goes over IWC's head: a blind eye would be turned to further whaling in the next three years and no fishing quota cuts would be imposed, provided Japan will compromise and agree to stop all whaling by 1988. Washington has apparently gone so far as to claim that Japan has already agreed to accept this offer. The subsequent announcement from Mr Sato suggests, however, that Japan will still fight on and try to win some further concessions from the United States — if legal action does not in the meantime undo what has already been achieved.

Alun Anderson

to abide by the rulings of the International Whaling Commission (IWC) that sperm whaling should end this year, and all commercial whaling next year. But Japanese officials claim they have agreed to end only sperm whaling by 1988 and that a ban on whaling altogether is only a US offer. And an angry statement from Hiroya Sanyo, the Fisheries Agency director general who headed the Japanese delegation, adds that the talks had been "unfair" and "outside the bounds of normal diplomacy".

Anti-whaling groups in Western nations are equally angry that Japan is now to be given until 1988 to end sperm whaling. An injunction is to be sought to force the US government to obey the Packwood-Magnusson Amendment to the 1979 Fishery Conservation and Management Act and impose cuts in Japan's fishing quotas the moment Japanese boats catch a sperm whale — and there are unconfirmed reports that two whales have already been caught.

The Packwood-Magnusson Amendment provides that when a nation "diminishes the effectiveness" of an international whaling agreement, it must be "certified" by the US government, which means that that nation's quota in the US 200-mile zone must be cut by at least half in the first year of certification and by 100 per cent in the second year. The outcome of court action is now likely to hinge on the meaning of the words "diminish the effectiveness", with the US government arguing that with the new agreement the effectiveness of the

Around the world in four years

OPERATION Raleigh, a four-year circumnavigation of the world that plans to mount over 150 scientific projects in more than 30 countries, was launched last week by its British patron, the Prince of Wales. The flagship of the expedition, named for Sir Walter Raleigh who sponsored the first English-speaking colony in North America 400 years ago, sailed from Kingston upon Hull last week for the Bahamas, on the first of 16 three-month legs.

The expedition is modelled on Operation Drake (1978-80) and is organized by the Scientific Exploration Society Ltd, a registered charity. Operation Raleigh will involve over 300 scientists, assisted by 4,000 selected young people, 75 per cent of whom will come from the United States and Britain. The ship is equipped with three scientific laboratories largely donated by Gallenkamp, diving facilities including a decompression chamber, a Marisat satellite communications system and a computer centre donated by Acorn Computers Ltd and Centronics, and will support both marine and land-based projects.

The first leg of the expedition to the Bahamas and Turks and Caicos Islands in the West Indies will include a biological

and geological investigation of the "blue holes" system of the Bahamian islands — underwater caves and tunnels carved out by the dissolution of limestone rocks by fresh water at a time (about 18,000 years ago) when the sea level was about 100 metres lower than it is now.

The Bahamas will also be the first site in a "reefwatch" programme to monitor the effects of sediment pollution on coral reefs. Coastal accumulation of sediment resulting from forest clearance reduces the amount of light penetrating the coral, which has an adverse effect on the photosynthesis of the symbiotic algae on which reef-building corals depend for their survival.

Operation Raleigh, operating as it does mainly from tropical latitudes, might be considered a "jamboree" for the scientists involved, but the main criterion used by the Scientific Research Committee in selecting projects — which must be more or less self-financing — was that the work should produce results suitable for publication in research journals. The young people who will provide semi-skilled assistance on the expedition were also subject to rigorous selection procedures.

Peta Pickering

Vaccinia virus

WHO to back vector vaccines

Washington

A SPECIAL advisory group to the World Health Organization (WHO) has approved an accelerated programme of research on recombinant vaccines using viral vectors. Such vaccines, now under development, might be used in mass immunization programmes where alternatives do not exist or are prohibitively expensive. Though yet to be approved by WHO's regular scientific advisory group, the decision puts to rest speculation that the reintroduction of vaccinia immunization programmes might be thought unnecessarily dangerous.

Vaccinia (cowpox virus) has long been a favourite organism for virologists, being easy to culture and safe to handle. With the elimination of smallpox, its use in vaccination was discontinued, because of severe reactions, sometimes fatal, that occur at the rate of 1 or 2 per million vaccinations. Furthermore, vaccinia can be transmitted by skin contact between people and from animals, albeit rarely.

Despite some reservations expressed at a workshop held last week jointly by WHO, the US Public Health Service and the British National Institute of Biological Standards and Control, the advisory group decided that the potential benefits of research into recombinant vaccines outweigh

the possible risk. Protection against a number of diseases has already been demonstrated in animals using vaccinia as a vector for antigens, including hepatitis B, herpes simplex virus type 1 and rabies (see for example *Nature* 311, 67; 1984). Although the safety of these vaccines has not been systematically studied, it appears that deletion of the thymidine kinase gene of vaccinia — which is replaced by the foreign gene — may make the virus even less easily transmitted than the normal type.

In its advice to WHO, the advisory group stresses the importance of developing alternative vectors likely to be of use against diseases of the respiratory tract and enteric diseases, including bacterial, protozoal and helminthic diseases. Because much early experience will be with animal vaccines, WHO is urged to establish links with the United Nations Food and Agriculture Organization to monitor veterinary results. And to avoid countries using different strains of vaccines haphazardly, WHO is invited to set up a collaborative centre for dissemination of information and storage of reference samples, probably to be located at the National Institute for Allergy and Infectious diseases at Bethesda, Maryland. **Tim Beardsley**

Israeli education

Palestinians push ahead

Rehovot

THE latest of Israel's institutions of higher learning, Ben-Gurion University of the Negev, has finally begun its academic year, two weeks behind schedule. It remains to be seen, however, how long Ben-Gurion and the others — all plagued by severe financial problems — will remain open.

To be sure, Ben-Gurion University, with an accumulated debt of US \$15 million, is worse off than the older, better established institutions. And this presumably explains both the delayed opening and the resignation (later withdrawn) of university president Shlomo Gazit. But with government support for higher education having dropped by one-third in recent years, the other schools are not in much better shape. The president of the Haifa Technion, Professor Josef Singer, has stated that "the Technion is still \$10 million short of even its reduced emergency budget and the conditions for an uninterrupted school year have not yet been guaranteed".

There is greater sympathy for the plight of the universities among members of the present government than existed in the last one, and education minister Yitzhak Navon, for one, has described their situation as "intolerable". But with all public spending being drastically reduced, including substantial cutbacks in even

defence and social welfare, it is unlikely that the government will be more generous than it has been in the past: in all probability, support will decline still further. This has forced the universities not only to undertake large-scale dismissals and reduce their purchases of vital scientific equipment, but also to shut down whole departments.

This development is taking place against the background of a dramatic increase in the educational level of Palestinians, both in Jordan and in the West Bank. During the 1983-84 academic year, 25,000 Jordanians and 13,000 West Bank Arabs passed the Jordanian matriculation examinations, about twice the number of matriculants as among the Jews of Israel, from roughly the same population of some four million people.

Educational advancement has been particularly spectacular in the territories under Israeli control since 1967. From 1967 to 1982, the secondary school population in the West Bank and the Gaza Strip increased by 106 per cent, while the general population went up only 23 per cent; and while in 1967 there were just a few hundred students in post-secondary programmes in those two areas, this year there will be nearly 20,000, a very high proportion.

Nechemia Meyers

Gromyko's prize

THIS year's Soviet State Prizes for science, announced as usual to coincide with the anniversary of the 1917 October Revolution — in November — went almost entirely to "cycles of works" carried out by teams of up to 12 persons over a long period of time. Only four prizes of the fourteen went to monographs by a single author: Ilya N. Vekua's "Some general methods of constructing different variants of the theory of shells" (1982), Dr Andrei D. Ado's "General allergology" (1978), Dr Valentin V. Seldov's "The East Slavs in the sixth to thirteenth centuries" (1982) and foreign minister Andrei A. Gromyko's "External expansion of capital: past and present" (1982).

Several of the "cycles" honoured cover two decades or more including B.B. Bokut' *et al.*'s "Highly effective nonlinear transformations of frequency in crystals and the creation of returnable sources of coherent optical radiation" (1963-82), I.N. Matrosov *et al.*'s "Elaboration of the method of Lyapunov vector functions for the analysis of stability and other dynamic properties of nonlinear systems" (1962-81) and K. P. Belov *et al.* "Magnetism and the electronic structure of rare-earth and uranium compounds" (1959-82). One citation seems to have been overdue — that of N. N. Bogolyubov, D. V. Shirkov and A. A. Logunov for their contribution "Method of renormalized groups in field theory", which carries the date 1955-56.

The citations do not make it clear just how far a cycle of work consists of genuine collaborative undertakings and how far it relates to parallel but separate work on a common theme. Co-winners are frequently scattered throughout several institutes, and even republics. Thus Bokut' *et al.* come from Gomel' University (Byelorussia), the Vavilov State Optical Institute, Moscow State University, the Institute of General Physics of the Soviet Academy of Sciences, Vilnius State University (Lithuania), the Institute of Electronics of the Uzbek Academy of Sciences and the Institute of Applied Physics of the Soviet Academy of Sciences. On the other hand, the team of geologists honoured for their complex study of the Baltic regions of the Soviet Union were all, to judge from their names, native to the Baltic republics (Latvia, Lithuania and Estonia) and for the most part are employed in research institutions of those republics, although one holds an all-Union post, as deputy director of the Marine Scientific Research Association of Engineering Geology. Likewise the team responsible for "Development of the theoretical principles of Soviet criminology" (1961-82) — a unusual subject for a state prize — all seem to be Moscow-based, although affiliated to such diverse institutions as the Academy's Institute of State and Law and the Moscow Police College. **Vera Rich**

United States in UNESCO

Withdrawal sanctioned by default

Washington

AN independent panel appointed to monitor the activities of the United Nations Educational, Social and Cultural Organization (UNESCO) has failed to find persuasive reasons why the United States should reverse its decision to withdraw from the organization at the end of this year. A final decision on US participation in 1985 must be made within the next two weeks, and barring an unexpected change of heart by the State Department, the withdrawal will go ahead as announced at the end of 1983.

The US decision was made because of management inefficiency at UNESCO and "politicization" of its programmes. The monitoring panel, chaired by Dr James Holderman, chairman of the US National Commission on UNESCO and president of the University of South Carolina, makes no specific recommendation on the question of withdrawal. However, its conclusions are thought not to be so compelling as to demand the positive action required to abort withdrawal at this late stage.

UNESCO has made a number of changes over the past year that go some way to answering the US criticisms. The most important, from the US point of view, was the recent agreement to freeze the 1986-87 budget at the 1984-85 level, a move long demanded by the Reagan administration. Furthermore, some of the more ideologically inspired language used to describe UNESCO ambitions on disarmament and human rights has been toned down, and new efforts have been made to evaluate programmes, both actions that indicate some sensitivity to US concern. But recently agreed management reforms are not thought by the United States to go far enough and there is considerable scepticism about how rapidly and effectively the agreed changes will be implemented.

Despite the partial successes, however, the United States has failed totally to bring about changes in the voting structure at UNESCO, and was deserted by its Western allies on this issue. As in other United Nations organizations, there is one vote per country, even though financial contributions are in proportion to countries' gross national products. The US contribution, at \$47 million, amounts to one quarter of UNESCO's total budget. Although UNESCO officials express confidence that programmes will continue even if the withdrawal does go ahead, the impact will be serious — especially if other countries follow the US lead. Britain and West Germany are wavering.

A separate assessment of how UNESCO has accommodated US demands is being undertaken by two subcommittees of the House of Representatives' Foreign Affairs

Committee, under Representatives Gus Yatron and Dan Mica. This assessment will not however be complete before February, and so will not bear on the withdrawal decision. In any event, the executive decision to withdraw would not easily be swayed by a congressional report. At one stage, the possibility was considered that the United States might delay its withdrawal by one year, which would bring it neatly to the end of a UNESCO biennial programme cycle, but that option has now been definitely discounted by Gregory Newell, Assistant Secretary for international organization affairs at the State Department.

The US decision had dismayed many who were working on scientific projects administered by UNESCO, which were thought to be largely innocent of the faults levelled at other programmes. The National Academy of Sciences earlier this year

produced a favourable assessment of the scientific benefits obtained through the agency. But the State Department maintains that in most instances US scientists will be able to continue their involvement with UNESCO programmes even after withdrawal, despite the lack of US representation at council level: domestic expenditure on the Man and the Biosphere programme, for example, is scheduled to be doubled or tripled over the next few years.

The State Department says it is also looking for ways to encourage technological development in developing countries that do not rely on UNESCO. How far these aims prove possible will depend on the seriousness they are accorded by the Office of Management and Budget, and on the willingness of UNESCO to cooperate after being jilted by its biggest paymaster.

Tim Beardsley

West German forests

Damage survey looks bad

Munich

THIS year's inventory of damage to West German forests, the first results of which were published earlier this month, shows further deterioration since last year. A half of all forested areas are now believed to be affected to some degree, compared with 34 per cent in 1983. But as yet there are no reports of forest areas in which the damage is complete.

The Forest Damage Inventory now completed was initiated by the federal government in Bonn, and is the third of a series begun in 1982. For the first time, the survey was based on a nationwide system of 4 km × 14 km plots. This year, however, the classification was refined so as to include five categories of damage (rather than three), numbered 0 (undamaged) to 3 (severely damaged) and 4 (dead).

The main criterion for assessing damage is the extent of loss of needles or leaves, with the discoloration of foliage a secondary consideration. The survey earlier this year was carried out by specially trained forestry personnel carrying colour photographs with which to check their observations.

Between 1983 and 1984, the most obvious change has been the increase of the proportion of West German forests in which the damage is classified as slight or moderately severe. Between the two most recent surveys there has also been a dramatic increase in the extent of damage in some degree to broad-leaved trees, with the percentage of affected beech trees increasing from 26 to 50 per cent between 1983 and 1984, and that of oak trees from 15 to 43 per cent.

In the latest survey, damage has been reported from throughout West Germany, but is most serious in the southern *Länder* of Bavaria and Baden-Wurtemberg. While the earlier surveys showed damage predominantly at high altitudes, the most recent survey shows damage everywhere.

As in previous years, the results of the forest inventory will not go undisputed. Although the methods used in 1984 have been more systematically applied throughout West Germany, the validity of needle loss as the main criterion for assessing damage is likely to remain controversial. But whatever is happening, there can be no dispute that the new type forest decline is increasing both in geographical extent and in severity.

Although the cause of the damage remains open to debate, in the past few years increasing attention has been paid to the importance of ozone in conjunction with other stressing factors as the chief agent of damage. So far, there have been no reports of forest tracts in which all trees have been killed.

L.W.Blank

Conditions for disarmament

SIR — J.N. Barkenbus and A.M. Weinberg (*Nature* 310, 95; 1984) were right to object that Stephen Salter's proposal for a superpowers disarmament negotiations algorithm (308, 490; 1984) assumes an unrealistic degree of collaboration between the protagonists. But it may slightly misleading to term the Salter scheme "original". Undoubtedly it is Mr Salter's own autonomous creation, and in its particular form it may also be entirely novel. It is certainly both elegant and economically structured. However, the "I cut — you choose" algorithm was suggested for this purpose in an article in *Journal of Conflict Resolution* 1963 by E. Singer.

The many differences between the Singer and Salter versions of what the former terms the "divide and choose" approach are probably of little interest, except to those who set more store by the contemplation of abstract negotiation models than I do. Suffice it to notice here that Singer's approach was to place all weapon retentions and weapon discards by both sides into a single population to be divided, and then to consider solutions to the difficulties this could pose. He also throws out the interesting suggestion that on-site inspection rights could be bargained for in the same or another similar structure, after they had first been portioned out in territorial units.

Unlike Salter, Singer did not so much see his scheme as replacing the antagonistic conduct of international relations, but rather as having to take its chances within the sordid arena of diplomacy. Thus he concludes: "Eventually, the realities of international negotiations must be confronted, and the diplomatic foxes must be set free to see if they can, without too much difficulty, play havoc with a bargaining model".

It is a pity that Barkenbus and Weinberg were unable to espouse the realism whose absence they regret in Salter. For it is certainly very naive to suppose, as their model does, that the arms race is about preserving a stable parity between the deliverable portions of populations of militarily undifferentiated "warheads". Their second and probably related assumption, also hard to share, is that we are dealing always and only with retaliatory forces. For once the idea of an attempted disarming first strike is admitted into the strategic calculations (as it always has been on both sides), it is no longer possible to claim that erection of a defensive anti-missile system can be directly offset by dismantling a proportion of one's own offensive missiles, to match the proportion of an enemy missile strike one expects to be able to block. For suppose Side A, with its new defensive system and, say, a matching 10 per cent reduction of offensive forces, were now to initiate a strategic first strike. The 90 per cent offensive force would be virtually as effective as before the reduction, and the defensive force,

facing only the decimated and disrupted remains of B's strategic offensive capability, would be very much more than 10 per cent effective because it would be handling a much smaller salvo of incoming warheads.

Since this is the worst-case scenario which would govern B's perceptions of A's new defensive deployment, it could be argued that the latter should be offset by a reduction of A's offensive arsenal proportional to the hypothetical "thinning" by which B's offensive forces would receive by the two processes of, first, an attempted disarming first strike by A, and second, the anti-missile effects of A's defences on B's subsequent retaliation. Thus A would have to pay for its 10 per cent effective defences with, say, an 80 per cent reduction of its offensive forces.

But of course A could not accept this, because it has to see the world as one in which B could be making the first strike, which demonstrates that there is no way to provide a "fair" mix of offensive and defensive deployments, except by making artificial and unrealistic assumptions to the effect that all nuclear strikes will always be retaliations, which is of course a useless option, despite Barkenbus and Weinberg's so boldly having taken it. R.I.P. BULKELEY
*Department of War Studies,
Kings College London,
Strand, London WC2R 2LS, UK*

SIR — The leading article "Targets for future arms control" (18 October, p.591) was both pessimistic and realistic. In a climate of mutual and reciprocal suspicion between the nuclear armed states, perhaps we should look to small, but achievable, measures that both build confidence and reduce further escalation of the nuclear arms race. I propose a measure that might achieve this and at the same time bolster the Non-Proliferation Treaty (NPT), which, you rightly comment, mercifully still holds, but only tenuously.

With 50,000 or so nuclear warheads worldwide, there is surely no need to add to this total. If so, then an effective "freeze" on fissile material production should be agreed to and implemented by each of the nuclear weapon states. A partial freeze of this sort was agreed by the US, UK and Soviet governments in April 1964.

In order to implement this, the nuclear weapon states would have to open up their reprocessing plants and plutonium/enriched uranium stockpiles to full inspection by a supra-national agency.

In his book *Face the Future* (1981, pp. 488-89), former British Foreign Secretary Dr David Owen has already argued this, basing his conclusions on his experience in office. With the Soviet Union recently accepting International Atomic Energy Agency (IAEA) safeguarding on some of its civil nuclear facilities and with the People's Republic of China joining IAEA,

the foundations of progress exist.

The French and British dual-purpose nuclear facilities, such as Marcoule and Phénix, and Sellafield remain a problem. Indeed Dr D. G. Avery, appearing on behalf of British Nuclear Fuels PLC, told the Sizewell B Inquiry (16 October) that the British Government and Euratom have been at loggerheads since 1973 over the non-accessibility of the Sellafield reprocessing line to physical inspection, despite Britain's accession to the Euratom treaty as a full partner.

Nonetheless, this problem certainly seems surmountable. This being so, it would surely strengthen the NPT, whose review conference in September 1985 is surely going to demand more equitable behaviour by the nuclear weapon states if others are not to withdraw, with the disastrous consequence of a nuclear free-for-all. Family planning

SIR — The reduction of the birth rate in China by one-half during the 1970s, reported in *Nature* (310, 612; 1984), is indeed welcome news. In view of high levels of fertility persisting in many areas of the world¹, what are the prospects for this feat to be duplicated elsewhere?

The primary requirement for a successful population programme must surely be the participation of most of the population in the programme; yet even in campaigns as vigorous as that in India, fewer than 1 in 4 eligible couples are protected². So the choice of method may be of secondary importance — pills and rhythm, for example, seem to have a similar overall impact on the fertility of acceptors³.

How can the scope of population programmes be broadened in societies which are less highly centralized than China's? A mass-marketing approach may be effective, as demonstrated by the unfortunate popularity of artificial infant feeding formulas in even the poorest areas. A more beneficial twist of this technique might involve the use of some other highly marketable health product in conjunction with a family planning campaign. Due to the threat of anaemia (see for example *Nature* 310, 615; 1984), iron supplements would be beneficial and would have a high level of appeal to women. By distributing supplements in packets of 28 and colour-coding them for the safe and unsafe days of the menstrual cycle, for example, many more women might be introduced to the practice of family planning than have been reached by conventional programmes.

Moral responsibility

SIR — In the leading article (*Nature* 25 October, p.692) on the expulsion of the ex-Nazi scientist, Rudolph, from the United States, the statement is made that “scientific research is a neutral, amoral enterprise *only* in a free society, one with a democracy capable of exercising social judgement over the propriety of end uses”. I would contend that you let us scientists off too easy, that we all have a moral responsibility, maybe even a duty, not to work on obviously immoral projects, such as, for example, those involving the murder of innocent people by chemical, biological, atomic-nuclear and even “conventional” weapons. Indeed, in the present international situation where warfare is not likely to be between individual soldiers but between peoples of contending states, it is the moral responsibility of scientists everywhere not to work on any project connected with waging war. I know the answer to this: that we in the democratic societies leave ourselves open to “nuclear blackmail”. But are you so sure of that, as much as you seem to be unsure of the great possibility that the ludicrous, to say the least, build-up of weaponry will not lead to a nuclear-driven mass destruction?

PHILIP SIEKEVITZ

Rockefeller University,
1230 York Avenue,
New York, New York 10021-6399, USA

Red Sirius

SIR — In the light of the discussions in *Nature* of Homer's wine-dark sea during the past four months, it was almost inevitable that the old problem of the red colour of Sirius would arise sooner or later (*Nature* 6 September, p.8).

However, the problem is soluble, from the testimony of several independent observers.

Arguing for a red colour of Sirius, only two referees may be regarded as reliable: the Roman philosopher Seneca (~70BC)¹ and the Alexandrine astronomer/astrologer Ptolemy (~AD150)². Neither texts, however, gives particulars of how these observations were made. All other Greek and Roman texts often presented as additional evidence³, speak only of the “fires” and “flames” of Sirius as it scorches the Earth during the “Dog-days”.

An Assyrian text (BM 118898)⁴, dating from the reign of Ashur-bel-kala (~1070BC), mentions a colour “red as molten copper”, but here Sirius is clearly stated to be rising and was therefore observed close to the horizon. The same applies to the observations described by the Arab poet Ibn Alrakka (as preserved by al-Biruni (1000)⁵).

Refuting such evidence are a number of contemporary texts citing a white or blue colour for Sirius. Astrological texts are very useful as stellar and planetary colours were closely observed for inferring future

events. The Greek astrologer Hephaestion Thebanus (~AD400)⁶, citing older Egyptian sources (2BC), discusses the various prognostications derived from the observed colours (golden, red, green and white) of Sirius at its heliacal rising. These colours clearly result from the effects of atmospheric extinction and scintillation on a white star near the horizon. Also, the Roman astrologer Manilius (~AD10)⁷ refers to the cold sea-blue quality of the rays of Sirius.

Most explicit are the observations found in the astronomical chapters of the ancient Chinese dynastical histories. Sima Qian (~90BC)⁸, Ma Xu (~AD100)⁹ and Li Shunfeng (~AD635)¹⁰, discussing the colours of the planets and selected standard stars, all assign to Sirius a white colour.

This evidence clearly shows that Sirius has never been intrinsically red during the past few millennia and is in full accord with the present evolutionary phase of the Sirius-system.

Italian slur rebutted

SIR — I was pleased to read in *Nature* (11 October, p.501) a news item wishing well to the new president of the Italian National Research Council (CNR). Indeed, Luigi Rossi Bernardi is a scientist first and a science administrator second, and his previous record is one of achievement through hard work, determination to assess quality and ability to develop rational policies. It is on these objective grounds that his appointment deserves praise. The sensitive reader will perceive this from the report. But it is unfortunate that in his opening paragraph Robert Walgate gives the impression that a major implication of the appointment is a transition from the “underdeveloped south” to the “better organized north”. To this the sensitive reader may react emotionally. However, since *Nature* is a

scientific journal, let us look at the issue scientifically.

In volumes 301–306 (1983) of your journal, there are eight papers from Italian institutions. Of these two are from the south, four from central Italy, one from the north. The eighth paper, interestingly, was a collaboration among laboratories in the south, centre and north (Catania, Perugia, Torino). Such a small sample has no claim to statistical significance, but it does not support the notion of a north-south dichotomy with respect to research output, which is what CNR is about. More important, if we look for example to modern biology, it is quite obvious that the main thrust over the past twenty years has come from laboratories in Naples, which, together with other CNR institutes that have developed from them, have today the highest concentration in the country of research and training programmes in molecular genetics and molecular biology.

Nobody will deny the existence of a north-south gradient in economic development in Italy, the historical reasons for which are complex and defy any facile analysis. But it does not become *Nature* to perpetuate ill-founded clichés. The first medical school in the Western world was established in Salerno, near Naples, more than a thousand years ago. Today, among the hardest-working scientists some are Neapolitans working in Naples. One of the challenges facing the new president of CNR is to provide the physical facilities required for a more productive outcome of their efforts and of the talent of their young students. I am convinced that Luigi Rossi Bernardi will be equal to this challenge.

LUCIO LUZZATTO

Department of Haematology,
Royal Postgraduate Medical School,
Ducane Road,
London W12 0HS, UK

SIR — It is unpleasant to read in a scientific journal such as *Nature* an article carrying racist and superficial judgements about Italy and the state of its science (“New Hope for Research Council” *Nature* 11 October, p.501).

Phrases such as “colourful Neapolitan presidency” or “underdeveloped south of Italy” betray profound arrogance and ignorance. You also say that the new CNR president “as a scientist” promises a scientific management of the research council that clashes with his political friendships (a truly scientific asset) and the most incredible statement of all — “. . . he comes from a medical department, medics being ‘the strongest mafia — in the best sense [my italics] in the Italian universities’”. I agree on the strength of that particular mafia. But I am sceptical of any “best sense” underlying that lobby. Mafia is mafia and no benefit can come from it to Italian science.

Genetic engineering and pharmaceuticals

from John Vane and Pedro Cuatrecasas

Genetic engineering now allows biological synthesis and large-scale production of several proteins with therapeutic potential. The principal challenge in this sphere is to identify new, medically and commercially significant targets — the province of cell biologists, physiologists and biochemists. In the future, genetic engineering will surely provide invaluable tools for the study of the molecular basis of cellular control and pathophysiology, which will permit biochemists and medicinal chemists to design novel medicines.

THE essential ingredients of profitable new ethical medicines are chemicals, which in the past have been extracted from plants (digitalis), animals (insulin, vaccines), living cell cultures (vaccines, interferon) or prepared by the synthetic chemist (most new drugs this century). What lies in the future with the advent of genetic engineering?

Medicines from organisms

The extraction of chemicals from organisms has been a source of important therapies for hundreds of years, giving us some of the most fundamental of today's medicines, including digitalis, curare, ephedrine and atropine. Extraction of the ergot fungus growing on rye led to Henry Dale's discoveries and investigations of acetylcholine, histamine and adrenaline. More recently, the extraction of moulds, initiated by the penicillin saga, has culminated in a whole series of antibiotics, the -mycins and the -sporins, for example. Very recently, avermectins have been discovered in extracts from micro-organisms.

The surface of the Earth continues to be combed for further novel sources of therapeutic agents, although such efforts have become less productive in recent years. In the past 15 years, the search has even turned to the bed of the sea, but the Roche experimental marine station, set up in Australia for that purpose, has now been closed. The US National Cancer Institute's search for natural products led to the discovery of potent plant alkaloids but the programme has been curtailed. Other interesting leads may arise from recent studies of Chinese medicinal preparations. But we may have to accept that the therapeutic natural products have largely been discovered.

How, if that should be the case, shall we maintain the therapies the natural products have provided? Digitalis, the cardiotonic drug, used in medicine in one form or another for at least 200 years and which stimulates the failing heart to beat better, is a good example. The "digoxin" of the 1990s will come from one or more of the following sources:

- The ground-up leaf of the foxglove, as at present.
- The leaves of "super-foxgloves" made to yield more digoxin than before, either by standard plant-breeding techniques or by genetic manipulation.

- A tissue culture technique, based on growing foxglove cells as a slurry or on using immobilized plant cells.
- Chemical synthesis of the complex active chemical in the laboratory and factory, provided that product is cheaper than the three above.
- Replacement of digoxin by a therapeutically superior simpler synthetic chemical that does a similar job, as evidenced by animal and clinical experiments.
- The discovery of an endogenous digoxin-like substance that we all make when healthy, but which is deficient in disease. It is possible that such a substance exists (the natriuretic hormone)¹ and that digoxin stimulates the sites on cells designed to react to this natural substance. The identification of such a substance would provide a different starting point for the synthetic chemist.

Digoxin is not a protein, and the genetic information required for its synthesis in the foxglove is probably so complicated that it is unlikely, in the foreseeable future, that gene transplants into other organisms will lead to cheaper synthesis. Thus, for digoxin, we can safely conclude that extraction of foxgloves (standard, super or slurry) will continue until such time as the medicinal and organic chemists provide better — cheaper, less toxic, more efficacious — alternatives. But that is likely to happen during the next decade.

The same general conclusion can be extended to other natural products, bleomycin or adriamycin, for example, for the skills and power of the medicinal chemists have now outstripped nature. Computer chemistry will speed this process.

Animal sources

Other natural medicines are extracted from animal tissues or animal cell cultures. Two kind of extracts are possible. The first is typified by insulin, where a useful chemical is produced from the glands of animals (cows or pigs) which are bred and killed for other purposes. Thus, insulin is a valuable by-product of a different industry. Fractions of different components are also made from human blood. A more macabre example is the extraction of human growth hormone from the glands of dead people. The second kind of extract is the basis of the vaccine industry, which has tradition-

ally relied on growing bacteria or viruses in enormous quantities, treating them in such a way that their pathological activity is lost but their capacity to immunize (immunogenicity) retained. When the resultant "soup" is injected into animal or man, the immune system reacts defensively to the antigenic content (usually a protein or carbohydrate) in such a way that the whole organism is prepared to defend itself against invasion by the living bacteria or virus. The soup sometimes contains live attenuated viruses which lead to actual viral replication in the host, thus eliciting a productive antibody response (as in mumps, measles, rubella, polio, yellow fever); such vaccines could not easily be supplanted by synthetic approaches, and they exhibit potent adjuvant activity and long-term protection.

Somewhere between the two examples are substances like interferon, interleukins, urokinase and tissue plasminogen activator with actual or potential therapeutic actions. These can be produced in quantity from human cells grown *in vitro*. For example, human α -interferon can be produced in commercial quantities by deep cell culture methods pioneered by The Wellcome Foundation.

Traditionally prepared vaccines would never meet the standards required of synthetic medicines, with the demand that the inactive ingredients should be characterized and that the active principle should be more than 90 per cent (and sometimes more than 99 per cent) pure. The antigen or active ingredient of a vaccine may represent less than 1 per cent of the material in a mixture of hundreds of unknown by-products of the bacterial, viral and animal material used to generate them.

It is in this overall field of protein chemistry that genetic engineering offers to provide directly applicable products of therapeutic value and commercial reward. Large protein molecules are, at present, too complex for the synthetic chemist to tackle, so that the biosynthetic route offered by gene-splicing is enormously promising for the large-scale production of these proteins. Furthermore, proteins of animal origin often differ slightly in chemical structure from those of human origin, so that when given to man for replacement or other therapeutic use, they may be recognized as "foreign" and thus lead to unwanted reactions. For this reason, an additional attraction of the

gene-splicing route is that it can provide human proteins. Many of these, such as insulin, interferons and growth hormone, have already been successfully prepared and are either on the market or in clinical trial. The major challenges lie within a limited number of potential candidates from which only a few may offer significant medical value and commercial potential.

Gene products

We are now seeing the commercialization of insulin and interferons derived by gene-splicing techniques. Human insulin is already on the market. However, it is still not clear whether the investment that has been made to fulfill this specific purpose will ever be justified by sales of human insulin alone. Immunogenic intolerance to bovine or porcine insulin (requiring treatment with human material) is extremely rare, the synthetic insulin appears to produce immunological problems of its own and, in any case, the present pancreas-extracted insulins are cheap. The extraction from the pancreas of animals is not only a side-product of the meat industry, but has also become a multi-faceted industry in its own right, yielding enzymes as well as insulin; until the enzymes as well as the insulin are more cheaply available from gene-splicing techniques, the very slight differences in side effects predicted for human insulin may not provide the necessary commercial edge. Moreover, some of the goals of genetically engineered "new" or different proteins can also be achieved by chemical modification (by traditional techniques) of available proteins (such as bovine insulin). Human insulin derived from gene splicing may turn out to be a "loss leader".

Biosynthetic interferons could well be different. There are aspirations that if a gene-spliced interferon can be made pure and commercially viable, it may be used in conditions such as the common cold² and for other viral diseases, including influenza, although present experience suggests that the side effects may not be acceptable for most of the self-limiting and mild viral diseases. Given that more refractory medical conditions (such as hepatitis and solid tumours) respond to interferons, they may be particularly attractive targets for, unlike insulin, (1) they are not available in any single tissue or organ for simple extraction (they are not stored in tissues); (2), they have proved extremely difficult to purify in significant quantities; (3) there are several chemically distinct classes (and probably subclasses) of the hormone and, (4), large amounts are needed for clinical experimentation simply to determine their specific utility.

Other human proteins also in the sights of the genetic engineers include growth hormone (but will it be commercially viable?), serum albumin, urokinase, plasminogen activator, factor VIII and lymphokines (the potential applications of

which are presently unknown). Most such potential medicines will need to be injected because of their chemical nature. Drugs available orally will always have more appeal than drugs given by other routes. Simpler but equally effective small molecules capable of synthesis by chemists will always be more attractive than complex proteins, no matter how synthesized. It is for these (and other related) reasons that the biosynthetic route, including gene-splicing, will always be threatened by advances in biology and biochemistry and by chemical techniques. In fact in most spheres of activity, the genetic engineering approach to the biosynthesis of specific molecules is a prelude to (and will encourage) development of superior and less expensive alternatives by organic chemists and biochemists.

The genetic engineering approach, coupled with Milstein's monoclonal antibodies³ and affinity methods for protein purification⁴, already offers an alternative method for the characterization of proteinaceous hormones, transmitters and neuropeptides of potential therapeutic importance. Many such hormones (enkephalins, endorphins, interleukins, morphine, lymphokines, transforming peptides, macrocortin) have been recognized in the past few years, and there are clearly many more to come. The tools of the genetic engineer will provide reagents that will contribute greatly to this field. Not only will the new techniques provide large quantities of pure peptides for study, but they will also assist in identifying and isolating the targets, or receptors, of their action. New and important therapeutic avenues must arise from this work. Recombinant genetic approaches will be invaluable for the study of cellular control mechanisms. Furthermore, recent advances in understanding the nature, chemical structure and function of numerous receptors provide essential information for the medicinal chemist. The ultimate therapeutic value of highly active molecules such as interferon, insulin, growth factors and lymphokines lies not so much in their end-use as therapeutic agents, but more in what they teach us about the disease process. It is in this context of new knowledge and understanding that truly selective and rationally derived new therapeutic agents will arise. Thus, understanding of the mode of action of peptide transforming growth factors, and the expression and target activity of oncogenes, may ultimately lead to the selective control of the malignant state.

Vaccines

Genetic engineering offers many opportunities for the development of new and improved vaccines. Some, like foot and mouth disease vaccine (FMDV) and hepatitis, are near at hand. Others, like a human malaria vaccine, are within sight⁵. The targets range from an attack on present markets such as FMDV through a range of

achievable new human and animal vaccines against bacterial, viral and protozoal infections, to still hypothetical vaccines that might make sheep the size of elephants, or prevent pregnancy. Those who side with prophylactic rather than therapeutic medicine can only be strengthened by the reality of gene-splicing. The progress that may be expected in the vaccine field is shown in Fig. 1. We are through phases A and B and into phase C. To understand the further progress which is possible needs only an elementary understanding of protein chemistry. The amino acids from which proteins are strung together are each about the same chemical size (molecular weight about 150) as one of Dale's transmitters, such as histamine or adrenaline. While the smallest of the proteins (or peptides) of 1 to 50 amino acids, such as angiotensin, may retain a linear structure, larger proteins (several hundred amino acids) wrap up into a three-dimensional complex, each with its own geographical characteristics determined by the type and number of amino acids.

Although it was originally thought that the ability of foreign proteins to stimulate the body to react defensively by producing antibodies (their immunogenicity) was linked primarily to the shape or tertiary structure of the whole molecule, studies with plant and bacterial viruses have shown that antiviral activity can be elicited by a small synthetic peptide corresponding to a region of the antigen involved in virus neutralization⁶. This work has been extended to animal viruses to induce an immune response to FMDV using a small linear part (14 amino acids) of the protein antigen⁷. This suggests that "a small peptide may be able to adopt a conformation approximating that which it assumes in the virus particle". Similarly, total synthesis of a diphtheria vaccine based on fewer than 20 amino acid residues has been achieved⁸.

Whatever may be the conformation needed to elicit antibody activity with such peptides, these results imply enormous consequences for the production of antigens by gene splicing techniques. For a peptide consisting of a score of amino acids is well within the scope of synthesis by medicinal chemists, and so is potentially a synthetic chemical rather than a bio-synthetic chemical or a "biological". Clearly, should this work be predictive for other single protein vaccines, the transition from phase C to phase D (Fig. 1) could well take place in the next few years.

Ten years ago, the idea of a peptide carrying activity into the body via the oral route was totally unrealistic, simply because the gut is designed to break down and provide a protective impermeable barrier for larger molecules (with, say, molecular weight exceeding 1,500). Now, orally active molecules based on a peptide structure are becoming common, through the skilful insertion of "unnatural" substituents. Two examples will illustrate

Fig. 1 The pattern of progress in vaccine production.

the point. The first is the development of the drug Captopril, an antihypertensive agent based upon inhibition of angiotensin converting enzyme. The first such inhibitors were peptides extracted from snake venom⁹. Knowledge of their structures led to the synthesis¹⁰ of a hybrid molecule which retained the required activity, but was orally active. The second example is in the field of enkephalins, where replacement of the naturally occurring L-amino acids (such as alanine) in the pentapeptide by the unnatural D-isomer¹¹ conferred a stability against enzyme degradation which allowed oral activity.

Thus, the transition from phase D to phase E (Fig. 1) is already theoretically possible. But a serious limitation to progress (even from B to C) is the need to strengthen the body's immunological recognition of and reaction to antigens by the use of adjuvants. This is easier to do in animals because adjuvants of a more toxic (or inflammatory) nature can be used. In man, anything worse than a sore arm for a few days would be unacceptable. For this reason, it is essential that better adjuvants be found. Perhaps even more important, we need to understand the mechanism of action of adjuvants in order to go to phase E. This has, surprisingly, been a generally refractory field of research.

Chemical synthesis

Virtually all new chemical entities of major therapeutic importance in the immediate past (such as propranolol, allopurinol, acyclovir, cimetidine) have arisen from chemical synthesis, and will do so in the future. There have recently been stupendous advances in biology and medicine, and numerous new molecular targets (enzymes, receptors, transmitters, mediators) are presently being identified as attractive and rational therapeutic points of leverage. At the same time, the ancillary tools are becoming ever more powerful. Furthermore, the automation of chemical reactions is allowing the synthesis of molecules of a type, and on a scale, unheard of even 20 years ago. This is especially true of the peptide field. On the one hand, the synthetic chemist is able to put together longer peptides, on the other,

the peptide needed to convey a specific antigenicity as a vaccine is getting smaller. It seems inevitable, therefore, that the medicinal chemist will eventually dominate prophylaxis as well as therapeutics.

Another enabling method that reinforces this conclusion is the computer chemistry or computer graphic technique¹². By visualizing the actual tertiary structure of receptors (also proteins), and the ways in which drugs interact with their active sites, the rate at which the chemist will be able deliberately to design heterocyclic molecules to fit into or modify such sites will be increased dramatically. These methods should yield standard principles applicable to the synthesis of unique custom-made molecules. For example, sufficient knowledge regarding the manner by which insulin (or interferon) interacts with its receptor at the molecular level should lead chemists to the design and synthesis of simpler, yet specific small molecules, not necessarily peptides, which will do the same (or a better) job as insulin (or interferon). The complex biological molecules will then no longer be needed as medicines.

Drug delivery

A new chemical entity, whether synthetic or biosynthetic, not only has to be active but also has to reach that part of the body where it is needed. Where an illness is associated with a particular organ (such as the liver or lungs), or with a discrete site (such as a solid tumour), it is advantageous to try to concentrate the drug in that tissue needing treatment, so that adverse effects on other tissues are minimized.

Simple ways of localizing or concentrating drugs have been known for many years. The inhalation of anti-asthmatic drugs theoretically takes substances directly to the organ concerned. A more exotic way of delivering drugs to a particular site or organ is to tie them to a messenger addressed to that organ. Antibodies directed at particular tissues have an obvious potential, and many groups are now searching for monoclonal antibodies that will attach specifically to cancer cells. A general antibody that reacts with cancer cells but not with normal cells will have not only diagnostic application but also the potential to carry a toxic message directed only at cancer cells. A further advance (if not a requirement, for selectivity) will be to direct the messengers to molecular entities on the cell surface which are normally destined to be internalized, or directly to the interior of selected cells, where they can do their damage.

This is an area of development in the biotechnology field of substantial importance. It is unlikely that, in the foreseeable future, medicinal chemists will find better messengers than can the immunologists. But the skills of the medicinal chemist will be needed to put the message into the hands of the specific chemical messengers and even to devise the

nature of the message, which may be radiochemical.

Future prospects

Over the next 20 years the various techniques associated with "genetic engineering" will infiltrate all fields of industry and science. Agriculture, energy supply and farming will all become more efficient. In science in general, and in those sciences applicable to the pharmaceutical industry in particular, there will be a substantial acceleration in the acquisition of knowledge of the working of different cells, and of the ways in which they communicate with each other. Monoclonal antibodies and gene cloning will also contribute significantly to the diagnosis and correction of genetic disorders. Importantly, the very knowledge which will be generated by the techniques will enable other disciplines, such as pharmacology, biochemistry and chemistry, to reap the fruits of progress.

At the same time, however, the synthetic chemical routes will eventually replace the biosynthetic routes offered by gene-splicing. For example, breakthroughs with synthetic chemical antiviral agents, such as Wellcome's new antiherpes drug, acyclovir¹³, will be followed by others that could make interferon obsolete. Similarly, insulin will be supplanted when there are discovered small molecules which mimic its action (as opioids, enkephalins and endorphins can resemble each other at receptor sites). Other simpler molecules will surely replace macrocortin, interleukins, endorphins, peptide hormones and so on.

From all this, it should be evident that the thrust of innovation depends on many disciplines working together. Creative biology and medicine must be the enabling force, by providing a body of knowledge which can be exploited by chemistry. In addition, the skills of the genetic engineer and the immunologist are essential not only to provide new (if temporary) prophylaxis and therapy but, much more importantly, to contribute to fundamental knowledge. For this reason, they should be integrated as closely as possible into the existing patterns of discovery rather than be isolated, as means to commercial ends, in their own compartments. □

Who will clone a chromosome?

The cloning of factor VIII, on which most haemophiliacs depend, is a technical triumph without parallel, but has left important questions unanswered. They rest for others.

By sad coincidence, this week there may be special interest in the publication of four long articles (pp.326 *et seq.*) describing how two groups in the United States have been able to isolate the gene responsible for human factor VIII, one of the essential components of the blood-clotting system. The significance of this development is described on p.326 by Professor George Brownlee and Dr Charles Rizza.

They explain that Genentech and the Genetics Institute have been able to clone the gene for factor VIII, to work out its nucleotide sequence, to infer the way in which the corresponding very large protein molecule is put together from amino acids and even to devise a system by means of which factor VIII may eventually be manufactured in large quantities.

This is also the week in which people in Australia have been startled by the news of the death of at least three infants as a consequence of transfusion with blood now suspected of being contaminated with the virus (called HTLVIII) responsible for acquired immune deficiency syndrome (AIDS), and in which a British haemophilia patient died from what appear to have been similar causes, the contamination of supposedly pure factor VIII by the same virus.

Although people in the United States have been familiar with such tragic happenings for at least two years, the spread of this bad news is a chilling reminder both of the dangers to us all embodied by the virus responsible for AIDS and of the urgency of the need for a process for producing factor VIII that may be free from risks of that kind. It is especially cruel that people suffering from haemophilia, already a sufficient hazard to peace of mind, should now be exposed to a further risk over which they have literally no control. Whatever the commercial interests of those responsible for this week's reports, their fleetness of foot will earn full-throated congratulation. Such is the promise of what we call genetic engineering.

Unfortunately, this week's clutch of papers will also help to give that field a less enviable reputation. In the application of molecular biology to practical affairs, it is for the time being clear that bigger battalions move faster. So is there a danger, already explicit in high-energy physics, that the list of the names of the authors of a scientific article will be longer than a reasonably succinct listing of its

conclusions? Readers must judge for themselves, recognizing as they do so the extraordinary character of what has been accomplished.

Hitherto, even the natural site at which factor VIII is synthesized has not been known (but the liver was always a candidate), the protein molecule is the largest whose genetic origin has yet been characterized and the circumstance that the protein (but not, yet, the glycosylation parts that naturally go with it) can actually be manufactured on a laboratory scale would not have been thought possible even at the beginning of this year.

Two sceptics' questions nevertheless arise, the first of which is whether, in the single-minded pursuit of something of undoubted value, those responsible for this staggering exploit may have neglected tantalizing scientific issues that could in the end turn out to be more interesting. And, perhaps, even more important.

Here is an example. To many readers, the most arresting feature of the stack of papers now published will be the information, mentioned almost in passing by both groups, that part of the factor VIII molecule now synthesized resembles in its amino acid sequence part of the molecule of a quite unrelated protein, the plasma protein called ceruloplasmin, whose function is for the time being largely unknown. Ceruloplasmin has two unambiguous properties — it is blue in colour (which is what its name implies) and it binds copper atoms (between four and six per molecule). But properly supplied with copper, ceruloplasmin is an oxidizing enzyme. The common guess is that its function in the human plasma is to convert ferrous (Fe^{2+}) into ferric (Fe^{3+}) ions. But nobody seems to have conclusive proof.

So why, teleologically speaking, should factor VIII resemble such a molecule? There are obviously several candidate answers. Perhaps factor VIII, like ceruloplasmin, also binds copper atoms in ways that are important to its function. (Molecules of factor V, the analogous component of the blood-clotting system, have at least one copper-binding site.) As yet, it seems, nobody has checked.

It is also, however, possible that evolution, always ingenious, may have hit on a way of using a pre-existing molecular structure (ceruloplasmin) as a way of helping blood to clot rather than its normal function, for the sake of argument that defying the second law of thermo-

dynamics, by banishing ferrous ions when they would normally occur. (Ferrous ions are an obvious threat to living things; ferrous chloride is virtually insoluble, they form free radicals easily.) The trouble is that is nobody, even now (and after reading pp.326 *et seq.*) can know whether factor VIII is a copper binding protein. Factor V is, but that could be a different matter.

In normal times, if the field were stagnant, these speculations would have been suitable material for a successful grant application (or several). So too would have been some of the other questions not merely unanswered but unasked by pp.326 *et seq.* Why (or, rather, how) does it come about that such a basic system as that responsible for the clotting of blood should require not one enzyme but several? (Because evolution has found it to be worthwhile, at the margin as the economists would say, to win a little extra efficiency at the cost of a great deal of extra elaboration, perhaps because the molecules required for these marginal purposes were already in essence available.) Why are the components of the blood-clotting system distributed so widely on the human chromosomes? (The same answer applies; they are where they happened to be, so to speak.)

But how does factor VIII function? What is the mechanism by which, in human plasma (and in association with another shadowy plasma protein, von Willebrand's factor) it catalyses the transformation of factor Xa? Nobody has begun to guess what may be at the bottom of this process. Nobody can be blamed, for even a few months ago the question would have seemed insufferably impertinent. Yet it needs to be answered, and quickly.

That raises the second question about the balance of this triumphant effort in the cloning of factor VIII that may yet come round to haunt the cloners — is it feasible to think of manufacturing by the kilo a molecule as large as that of factor VIII without risking that it will emerge corrupted, or as bad, ineffective, from the production line? Obviously, the genetic engineers would prefer to be manufacturing a simpler molecule, one related to the molecule whose structure had now been described, as a few amino acids in an antigenic molecule may represent the biological activity of the entire structure. Will that be feasible? Time, at the worst, will tell. Otherwise, a little research may make the question answerable.

John Maddox

Biotechnology

Clotting factor VIII cloned

from George G. Brownlee and Charles Rizza

ONE of the most exciting and ambitious goals of the biotechnology industry has been achieved. In papers that begin on page 326 of this issue, both Genentech, assisted by Tuddenham and colleagues of the Royal Free Hospital, London, and Genetics Institute, assisted by Fass and Knutson of the Mayo Clinic, Rochester, report the cloning of DNA for human blood clotting factor VIII:C and the production of the factor from cloned DNA expressed in mammalian cell lines.

Clotting factor VIII:C is the name given to the protein that is absent or defective in patients with classical haemophilia (haemophilia A), a sex-linked bleeding disorder of about 20 per 100,000 males. In the blood stream, factor VIII:C is associated with another protein, known as von Willebrand protein or factor VIII-related antigen, but factor VIII:C is solely responsible for the clotting activity of the complex (which is loosely termed factor VIII). Injection of factor VIII obtained from donor blood allows haemophiliacs to be successfully managed. But, unfortunately, the factor VIII preparations in use at the moment carry a high risk of transmitting blood-borne viruses such as non-A, non-B hepatitis virus. The virus that is thought to cause AIDS may also contaminate preparations and, although relatively few haemophiliacs have been affected so far, the fear of the disease has caused great anxiety to patients, their families and their doctors. A genetically-engineered factor VIII:C derived from a source other than blood should be free of such viruses. It should also be cheaper.

Both groups have used similar methods for the DNA cloning and expression of factor VIII:C and report very similar results. Oligonucleotide probes were synthesized on the basis of small sections of the amino acid sequence of purified factor VIII:C (either pig or human in origin), and used to screen an appropriate library of genomic clones to identify part of the factor VIII:C gene. The gene itself turned out to be extraordinarily long (180 kilobases), to have 26 exons and to occupy an estimated 0.1 per cent of the X chromosome (see Gitschier *et al.* on page 326 for further details).

For expression of protein it was necessary to isolate cDNA clones. These were obtained either from a human T-cell hybridoma line (Genentech) or from human liver (Genetics Institute) and sequence analyses allowed the derivation of the entire 2,332 amino acid sequences of the mature protein. Both groups (but see Vohar *et al.* on page 337 for an extended discussion), note that the protein is highly glycosylated and has an obvious domain

structure with predictable homology to another clotting factor, factor V, but also an unpredicted homology to ceruloplasmin — a serum protein believed to be involved in copper ion transport in the blood. The protein sequence also allows the definition of the main sites that are cleaved by thrombin in the process of activation of factor VIII:C.

The expression of factor VIII:C in mammalian cells required the reconstruction of a full length cDNA clone and its attachment to a viral promoter sequence. When this construction was introduced into either a hamster kidney cell line (Genentech) or a monkey kidney cell line (Genetics Institute), a human factor VIII:C-like activity was secreted into the media in which the cells were grown. The concentrations of factor VIII:C-like activity in the media were about one per cent (Genetics Institute) or seven per cent (Genentech) of the normal plasma concentration as assayed by a sensitive biochemical test based on the activation of factor X and hydrolysis of a chromogenic substrate. Furthermore, both groups showed that the secreted activity (further purified by affinity chromatography at Genentech) was able to correct the clotting time of plasma from a haemophiliac. Evidence that these assays are indeed a measure of factor VIII:C and not of some other clotting factor or non-specific activity, was provided by two additional tests carried out by both groups. In the first, the clotting activity was shown to be increased by

thrombin, a normal physiological activator of factor VIII:C. In the second, it was shown to be inhibited by specific factor VIII:C antibodies. The Genentech group also showed that, like authentic factor VIII:C, their substance bound reversibly to the von Willebrand protein immobilized on an affinity column and that its activity was destroyed by protein C — a serine protease of plasma that can inactivate factor VIII:C.

What is the outlook for treatment of haemophiliacs? It is clear from previous experience with genetically-engineered products that we must anticipate some delay, perhaps 3–5 years, before a safe, effective and clinically-tested product is on the market. The expression of factor VIII:C reported by both groups is very low and it is probable that more effective vectors or host-cell systems will have to be devised. Effective large-scale tissue culture and purification methods will also have to be developed. These may differ from existing procedures for purification of factor VIII from blood. We emphasize the need for a high purity product to guard against the possibility of any pathogenic material from the culture being introduced into haemophiliacs. It would be unacceptable to eliminate the risk of AIDS but substitute a new hazard. There remains the possibility that the genetically-engineered factor VIII:C, although of proven activity in a test-tube assay, may not be as effective *in vivo*. This can only be adequately tested by clinical trials of the product, the outcome of which must be eagerly awaited. □

Astrophysics

Evolution of star-planet systems

from Geoffrey Bath

A PROBLEM at the heart of stellar astrophysics is the role of angular momentum in the evolution of stars. This statement may seem controversial, given the profound success of stellar evolution theory in describing quantitatively the nucleosynthesis of the elements and the evolutionary transformation in the structure of stars as they perform their function as cosmic alchemists. The theory of stellar evolution has been largely developed without involving rotation in any major way. But a recent paper by M. Livio and N. Soker (*Mon. Not. R. astr. Soc.* **208**, 763; 1984) raises the dramatic possibility that the evolutionary fate of many single stars accompanied by planets could be both binary star systems and exploding variables.

Certainly, in the case of the Sun, present angular momentum, if rotation is uniform,

is quite unimportant in determining structure or immediate evolutionary future. The Sun cannot, however, be considered as an isolated unit; it is only one part — albeit by far the most massive part — of the Solar System. The angular momentum of the planets is sixty times greater than that of the Sun's own, assuming solid-body rotation in the inner core. Furthermore, the initial solar nebula, with a minimum mass of some 3 per cent of the Sun's mass, must have possessed an even greater fraction of angular momentum.

In the case of binary stars, angular momentum plays a very important part in determining their present binary state and subsequent evolution. In binaries, angular momentum decreases with decreasing separation. Even for W Ursae Majoris

stars, however, in which two relatively low-mass and approximately main-sequence stars are orbiting in physical contact, exchanging energy and surrounded by a common envelope, the angular momentum is hundreds of times greater than that of the Sun. Since more than one-half of all stars in the Galaxy are binaries, then if potential planetary systems around single stars are ignored, the significance of angular momentum is evident.

It was angular momentum considerations of these sorts that led Otto Struve in the 1940s to make the radical hypothesis of an evolutionary sequence that goes from giant binaries to dwarf binaries, and then to single stars with accompanying planets. He envisaged this being a result of the progressive dissipation of energy and loss of angular momentum associated with turbulence and differential rotation that von Weizacker was then advocating. As a general evolutionary theory Struve's notion has to be rejected, largely on the grounds that the dissipation time scales are too long in general to compete with nucleosynthesis as the main process of stellar ageing. There is incontrovertible evidence, however, that at least some stages of Struve's sequence have been significant and account for the formation of at least one important class of stars, the cataclysmic variables — though how is still a matter of debate.

Cataclysmic variables are binaries composed of a main-sequence star and white dwarf companion. The stars are so close that material from the surface layers of the distorted, pear-shaped, but otherwise apparently normal main-sequence star is being gravitationally captured by the white dwarf. Cataclysmic eruptions characterize these stars as novae and related exploding stars, generated both by unstable bursts in the mass transfer process and through runaway nuclear fusion reactions in the accreted hydrogen-rich material on the white dwarf surface.

One outstanding problem is the origin of these variables. Why is a white dwarf, which is formed in the deep interior of a red giant, now so close to a main-sequence star? In order to allow its precursor giant to form, the separation there must have been > 200 solar radii ($R_{\odot}$), whereas now it is $\approx 2 R_{\odot}$. Evidently either angular momentum has been lost, and lost relatively rapidly, or an extreme mass ratio originally allowed large separation with the present quota of angular momentum.

Livio and Soker have been exploring in some detail the second hypothesis, as originally advanced by P. Eggleton. They have examined the interaction of a planet immersed within a red giant's extended envelope. As it orbits within the envelope, tides are raised, viscous drag leads to dissipation and loss of orbital energy, and in certain conditions mass may be accreted efficiently. As a result, the planet acts as a catalyst, spiralling in through the envelope and accreting some fraction of the stellar

material as it does so. Livio and Soker find that the final mass of the planet is almost independent of the initial planet's 'seed' mass and is $\approx 0.14 M_{\odot}$, whereas the separation falls from $400 R_{\odot}$ to the range $8.6\text{--}0.5 R_{\odot}$. In this model for the creation of cataclysmic variables, loss of angular momentum is not invoked. Rather it is the change from the extreme mass ratio of a planet-giant system to the less extreme dwarf-white dwarf system that drives the two components together.

The present treatment is limited to somewhat *ad hoc* envelope conditions and assumptions of angular momentum conservation. Nonetheless, the principles by which a planet or intermediate dwarf may be converted into a low-mass main-sequence star, via the stripping of a red giant envelope to expose the degenerate core, are clearly revealed. More recent work by the same group shows that the

same features are present when the giant envelope reacts self-consistently to the spiralling process. If this is proved by future observational tests to be the origin of cataclysmic variables, Struve's ideas will have found some support, but with the important difference that the evolution from a wide planetary system to close interacting binary is in the opposite sense to Struve's early thesis. But then stellar evolution of single stars was long thought, erroneously, to proceed from red giant to main-sequence dwarf. With the idea that the fate of our own Solar System might conceivably lie as a cataclysmic nova, a new possible future for the Sun has to be confronted. □

Molecular biology

Multiple levels of gene control in eukaryotic cells

from Geoffrey North

How can a gene be regulated by steroid hormones in some cells of a chicken and not in others, in which it is either expressed constitutively or not at all, even though both categories of cells may contain perfectly functional steroid hormone receptors? And how is the level of expression of immunoglobulin heavy-chain genes increased approximately 30-fold when B lymphocytes differentiate into antibody-secreting plasma cells? The possible answers to these puzzles, which emerged at a recent meeting*, illustrate how multiple levels of control combine to ensure that the right genes of eukaryotes are expressed at the right times, in the right amounts and in the appropriate cells.

The pattern of immunoglobulin heavy-chain gene expression in B cells has been presumed to be at least partially accounted for by the 'enhancers' that were discovered last year between the joining (J) and first constant (C_{μ}) exons of both human and mouse genes¹⁻³. These were the first gene-regulatory sequences of eukaryotes to be discovered that manifest cell-type specificity. Typically for enhancers, they can stimulate transcription of a gene whichever orientation they are in and at variable distances upstream or downstream from the gene. However, as W. Schaffner (Institute für Molekularbiologie, Zürich) explained in Heidelberg, this clearly cannot be the whole story.

The original evidence that these enhancers are cell-type specific came from experiments in which they were linked in

various ways to a test gene, such as that encoding β -globin, which was subsequently shown to be efficiently expressed in transfected B cells but not in other cell-types, such as fibroblasts or epithelial cells. However, Schaffner reported that a test gene (the T-antigen gene) linked to a mouse immunoglobulin heavy chain gene enhancer is expressed as efficiently in pre-B and B cells as in plasma cells, even though the level of expression of the endogenous immunoglobulin heavy-chain gene increases dramatically as B cells are stimulated to differentiate into plasma cells.

This observation has led Schaffner and his colleagues to investigate just how the rates of transcription of the immunoglobulin heavy-chain gene compare in pre-B, B and plasma cells. Surprisingly, the rates turn out to be identical at each stage of B-cell differentiation, so the higher level of immunoglobulin heavy chain mRNA in plasma cells than in pre-B and B cells must be the result of some post-transcriptional control mechanism, such as a change in RNA stability.

Further support for this inference comes from the observation reported by M. Neuberger (MRC Laboratory of Molecular Biology, Cambridge) that when the immunoglobulin heavy-chain gene itself is reintroduced into pre-B, B or plasma cells under the control of its own enhancer, its level of expression reflects that of the endogenous gene. Neuberger also reported evidence that the enhancer is not the only component of the immunoglobulin heavy-chain gene to manifest cell-type specificity: the coding region of a β -globin gene linked to the promoter of the immunoglobulin

*'The Control of Transcription in Eukaryotes', 10th annual EMBO symposium, 24-27 September 1984, European Molecular Biology Laboratory, Heidelberg, FRG.

heavy-chain gene (which flanks the 5' side of the variable, *V*, region) is properly transcribed only in B cells, even when linked to the SV40 enhancer, which is known to work in many different cell-types. Neuberger suggested that this specificity may be conferred by the conserved sequence that has been found upstream of all immunoglobulin gene *V* regions sequenced to date⁶.

The precise role of enhancer sequences in immunoglobulin gene expression has also been brought into question by two observations. First, the λ light-chain gene does not seem to have one, and second the translocations that frequently have juxtaposed immunoglobulin genes with the *c-myc* gene in B-cell malignancies more often than not have removed the enhancer to the reciprocal translocated chromosome (see ref. 7 and references therein). The implication of the latter observation is that the immunoglobulin gene enhancer cannot be directly responsible for the deregulation of the *c-myc* gene that is thought to have played a key role in these types of cellular transformation⁷.

A similar apparent lack of a requirement for an enhancer is shown by the continued heavy-chain gene expression after spontaneous deletion of regions of the gene that include the enhancer^{8,9}. For one of these cases, that of a δ heavy-chain-producing mouse hybridoma cell line⁹, Schaffner's group has preliminary evidence that the cloned enhancerless gene must be linked to a new enhancer in order to be expressed when it is reintroduced into B cells. On that basis, Schaffner suggests that enhancers are perhaps required for the establishment of transcription, but are not essential for its maintenance. As Schaffner pointed out, this could account for the apparent lack of requirement for an enhancer for the deregulation of translocated *myc* genes.

If this is so, then why are genes that are turned on by steroid hormones turned off again when the hormone is withdrawn, given that the sequences upstream of genes that confer steroid-responsiveness now seem to be just like the inducible enhancers^{10,11}? A possible clue may be in some results reported in Heidelberg by P. Chambon (Institut de Chimie Biologique, Strasbourg).

The principal aim of the experiments reported by Chambon, like those reported by G. Schutz (Institute of Cell and Tumor Biology, Heidelberg) was, however, to answer the puzzle posed in the first sentence of this article — how can one account for the different patterns of expression of steroid-inducible genes in different cell types, all of which contain the appropriate steroid hormone receptors.

For example, the chicken ovalbumin gene is induced by oestrogen in oviduct cells, in which the vitellogenin gene is permanently inactive, whereas in liver cells the ovalbumin gene is permanently inactive and the vitellogenin gene is oestrogen-inducible. Perhaps even more puzzling is

the chicken lysozyme gene, which can be induced by oestrogen, progesterone, testosterone or glucocorticoids in oviduct cells, but is permanently inactive in fibroblasts (which contain glucocorticoid receptors) and is expressed constitutively, albeit at a low level, in macrophages.

From an analysis of the expression in cultured cells of microinjected hybrid genes comprising the SV40 T-antigen coding region linked to flanking sequences of the chicken ovalbumin genes (Chambon) or lysozyme genes (Schutz), it seems that, in addition to hormone-responsive sequences, the genes are controlled by other cell-type specific sequences that further restrict their expression. However, in view of the observation of Chambon's group that the ovalbumin flanking sequences allow constitutive gene expression in injected liver cells, the inactivity of the endogenous gene in liver cells remains a puzzle. Chambon suggests the answer may lie in the establishment of domains of permanently inactive and potentially active chromatin during development.

Chambon also reported that hybrid genes containing up to 295 base pairs of the upstream flanking sequences of the ovalbumin gene are constitutively expressed in oviduct and liver cells, but that if 420 base pairs of flanking sequence are used, expression is blocked in oviduct, but not in liver cells. This block can be overcome by steroid hormones or by including an SV40 enhancer element in the microinjected construct. On the basis of these data, Chambon postulates that oviduct cells contain a repressor that recognizes the upstream 'blocking sequence' and keeps the level of expression of the ovalbumin gene minimally low in the absence of hormone. Could it be that such a repressor also has the role of re-establishing a requirement for enhancer-induction following hormone withdrawal?

The notion that enhancers may be required only for the establishment, and not for the maintenance, of a state of transcription is, however, somewhat difficult to reconcile with a model put forward by K. Yamamoto (University of California, San Francisco) to account for some recent results obtained by his group and which may also provide an explanation of some of the remaining puzzles of the regulation of steroid-inducible genes. In essence, Yamamoto reported that pairs of different enhancer sequences in combination can have synergistic effects on the genes to which they are linked, and that these effects depend on the precise nature of the promoter from which transcription of the gene is initiated.

Yamamoto suggests that these observations can be explained if different enhancers stimulate the supply to the promoter of different specific transcription factors, the synergism resulting from a change in the factor that is rate-limiting for transcription in the presence of one or

other, or both, the different types of enhancer. Following this line of argument, then, the failure of steroid hormones to increase the low constitutive level of lysozyme gene expression in macrophages could be due to the absence of some other factor which is necessary, though not sufficient, to enhance transcription.

This is all speculation, however, and in truth we still have little idea how even steroid hormone-induced enhancers activate transcription. Even the role of the steroid hormone is still obscure for, as M. Beato (Institut für Physiologische Chemie, Marburg) and W. Schrader (Texas Medical Center, Texas) explained, although the presence of hormone is required for the stimulation of transcription, the hormone-receptors bind quite happily to their specific sequences in the absence of hormone. Hopes that some of this ignorance might soon be dispelled were raised in Heidelberg by Yamamoto's news that his group has cloned cDNAs encoding the rat glucocorticoid receptor. □

100 years ago BACTERIOLOGY

AMONG the most striking of the recent rapid advances of science is the development of what we may term bacteriology. While some of this work has been done in this country, by far the greater part has been done abroad, more especially in Germany and France, where its importance is recognised, and where special facilities are afforded by the Governments and various public bodies. In Germany especially, besides the laboratory, supported by the Government, in which Dr Koch works, a number of similar institutions are being established throughout the country; and in France the laboratories of Pasteur and others are established and supported by the Government and by various municipal authorities, every facility for carrying on these researches, and the necessary funds, being provided. In this country, on the other hand, there is no laboratory of the kind, and what work has been done has been by individual investigators working at their own expense and often without suitable accommodation.

Carbon cycle

Surprise from the shallows

from M. Whitfield

A RARE new insight into the workings of the carbon dioxide cycle is offered by the paper of Byrne *et al.* on page 321 of this issue and its companion, from the same group, which is published in this week's *Science* (226, 1074; 1984). In suggesting, from observations in the North Pacific, that the flux of calcium carbonate shells from the surface layers into the deep oceans has been grossly underestimated, these papers imply a significant shift in our understanding of the oceanic carbon dioxide system.

From an analysis of the particles that settled in large conical traps, deployed at various depths for only a day or so, Byrne and his colleagues were able to show for the first time that pteropod shells, which are made of aragonite — the most soluble form of oceanic calcium carbonate — contribute a flux of calcium carbonate to the deep ocean which is at least as great as that provided by the calcite shells of the foraminifera and coccolithophorids. Furthermore they show that, unlike calcite shells which fall into the sediment and then redissolve only slowly, most of the pteropod shells dissolve in the water column. Earlier measurements had been inconclusive; tow-net sampling had allowed no estimate to be made of the settling rate of pteropods, and long-term sediment traps had inadequately registered the presence of pteropods because their shells had dissolved in the weeks or months before the traps were recovered.

As the shells settle out of the surface layers into deeper water, they resist progressively more corrosive conditions until reaching their lysocline, where they begin to dissolve. Typical lysocline depths for the North Atlantic are 3.2 km for aragonite and 4.6 km for calcite. For the older and more acidic deep waters of the North Pacific, the lysocline depths are typically 0.6 km for aragonite and 0.8 km for calcite. Although calcium carbonate dissolves at and below the lysocline it can still be found in sediments down to the compensation depth, where rates of settling and dissolution just balance.

For each mole of calcium carbonate dissolved, one mole of carbon dioxide is converted into bicarbonate (resulting in an increase in oceanic alkalinity). The new findings make it possible to establish a realistic alkalinity balance for the oceans. Moreover they suggest that the oceans might act as a more rapid and effective sink for fossil-fuel carbon dioxide than had been thought possible when attention was focussed on the dissolution of calcite from the ocean sediments. In that case the response time is measured in centuries or millennia because of the slow circulation of

the carbon dioxide-rich waters down to the compensation depth. To dissolve a significant amount of calcium carbonate, these acidic waters must penetrate the sediments, still further slowing down the process.

The new observations indicate that 5-20 per cent of the smaller pteropod shells will have dissolved by the time they have reached a depth of 1,000 m. This dissolution provides a ready explanation for the mid-water alkalinity maximum that is observed in North Pacific waters substantially supersaturated with respect to calcite, which has previously been ascribed to the possible, but rather unlikely, long-distance transport of high alkalinity water from the edges of the ocean basin.

To close the circle, it is also necessary to consider the enhancement of shell dissolution by the increasing oceanic concentration of carbon dioxide that is resulting from the burning of fossil fuel. The new observations make it clear that this carbon dioxide has only to penetrate to the aragonite lysocline for it to have an effect. Model calculations suggest that it has

already reached a depth of 300 m — close to the aragonite lysocline in the North Pacific — as the result of the slow downward mixing of surface waters. If the dissolution of pteropod shells in relatively shallow waters is enhanced in this way, there will be a corresponding reduction in the alkalinity of the deeper water. In turn, this will accelerate the dissolution of the calcite shells and the larger aragonite shells in the sediment. Furthermore, as the falling shells begin to dissolve, their rate of fall will be reduced and hence their dissolution will become progressively more complete.

On a global basis, this process could accommodate up to one fifth of the current flux of fossil-fuel carbon dioxide and would therefore be much more important than the dissolution of shallow-water, magnesium-rich calcites that has previously been considered the best candidate to account for any rapid response. As oceanic carbon-cycle models become sufficiently sophisticated to incorporate biological processes in a realistic fashion, it will be instructive to see to what extent the oceanic uptake of fossil-fuel carbon dioxide will be influenced by the shift in the alkalinity balance implied by the flux of pteropod shells to the deep ocean and by their tendency to dissolve in transit. □

Cell biology

A spectrum of spectrins

from A.J. Baines

SOME two years ago I alluded in these columns to the discovery of analogues of the red cell membrane skeleton protein, spectrin, in unexpected places¹. Since then they have been looked for and found — at least by the somewhat rudimentary technique of immunological cross-reaction — in almost every kind of cell that the imagination of cell biologists can run to.

The outsider, trying to follow the trail of discovery, is apt to be put off the scent by a multiplicity of terminologies. Not only are several names (tissue spectrin, caldesmon, fodrin) still in use for the spectrin-like proteins of non-erythroid cells, but we now have multiple names for their subunits too. For instance, the smaller subunit of brain spectrin, because it binds to the membrane-associated retaining protein, ankyrin, and hybridizes with the larger, alpha subunit of either brain or red cell spectrin, is sometimes termed beta by analogy with the erythrocyte beta chain (for example ref. 2). On the other hand, its electrophoretic mobility in SDS differs from that of erythrocyte beta chain and peptide maps of the two are quite distinct, so what seems to be the same peptide turns up elsewhere under the designation gamma (for example, ref. 3). Ultimately, the relationship between these polypeptides will need to be resolved by

direct comparison of sequences, using that of the greater part of the red cell spectrin molecule⁴ as the standard.

So what does spectrin do in different cells? In parallel with its tissue distribution, some indications of the cellular functions in which it may be involved have accrued. Originally it was supposed that spectrin and its associated proteins, which together make up the red cell membrane skeleton, would perform much the same function in, say, a brain cell as they would in a red cell. Thus it was conceived that a plasma membrane needed a supporting cytoskeletal apparatus to prevent its disintegration, although, to be sure, no brain cell has to withstand the rigours endured by the red cell in circulation.

Complicating this attractively simple model has been the discovery that tissue spectrins are able to enter into associations with proteins not present in the mature red cell, as well as being able to bind protein 4.1, actin, ankyrin and calmodulin. They can bundle microtubules⁵ and bind to at least one of the microtubule-associated proteins (tau)⁶, activities which may be reflected in the antigenic cross-reactivity of spectrin with MAP II, another microtubule-associated protein⁷. Brain ankyrin also binds to microtubules⁸, although in

this case an interaction with tubulin dimer is suspected as well: here again there is cross-reaction with another microtubule-associated protein, MAP I⁹. Brain spectrin and ankyrin may indeed be the first examples of membrane-associated microtubule-binding proteins. An indication of an interaction between spectrin and intermediate filaments has come from evidence that when anti-spectrin antibodies are microinjected into cultured cells, not only is spectrin precipitated, but the organization of the intermediate filaments is disrupted¹⁰.

Support for the idea that spectrin is somehow involved in maintaining the physical state of membranes comes from the elegant immunofluorescence studies of Koenig and Repasky¹¹, who show that isolated axons are enriched in spectrin where they are not enclosed by a myelin sheath, that is at the nodes of Ranvier and the synapses. It therefore seems that spectrin is involved in the generation and maintenance of plasma membrane domains. However, this cannot be the whole story since the same group has discovered an association between spectrin, as well as calmodulin and F actin, and the rapidly moving axonal particles (motile varicosities), which are seen in axons regenerating *in vitro*¹². This suggests that the role of spectrin also encompasses the linkage of organelle membranes with cytoskeletal elements. Aunis and Perin¹³ have added a further twist by suggesting the implication of spectrin in chromaffin granule exocytosis. If spectrin is indeed involved in exocytosis then its concentration at the synapse could be taken to imply a role in neurotransmission. A further recent conjecture is that the cleavage of spectrin on post-synaptic membranes, triggered by depolarization-induced events, may be involved in memory storage¹⁴.

So in answer to the question of the cellular functions of spectrin, a general role is now discernible. Spectrin seems frequently to link cytoskeletal elements to plasma or other (for example exocytic) membranes, or to regulate that linkage. Cells may use the linkage in a variety of ways, including the generation and stabilization of plasma membrane domains, the facilitation of intracellular transport (leading in certain cases to exocytosis) and the regulation of the activities of transmembrane proteins. Watch this space. □

Devonian vertebrates from South America

DEVONIAN vertebrates have been recorded from every continent except South America, where only a few fossils have been tentatively referred to this group (Janvier, P. *Program. intern. Correlat. geol.*, La Paz 44 1; 1978). The most convincing of these is a footprint of an amphibian, from the Devonian of Brazil. Lower and Middle Devonian sites of western and central Bolivia have now yielded scales of agnathans, spines and scales of acanthodians and sharks, and a skull and plates of a placoderm.

The figure illustrates two of the Devonian fishes we have excavated. The Middle Devonian Sicasica Formation, which extends south of La Paz on the Altiplano (site 1 on the map) yielded a well preserved braincase and the jaws of a rhenanid (a), a rare group of placoderms (armoured fishes) known from the Devonian of Europe and North America. There are close similarities between these fossils and a complete rhenanid, *Gemuendina stuerzii* (b) excavated from the Lower Devonian of Hunsrück, FRG. South-east of the Altiplano in the Chuquisaca district (site 2 on the map), the Lower Devonian Catavi Formation crops out along the Rio Grande at Seripona. There, a rich bone-bed has yielded remains of acanthodians, sharks and thelodonts, a group of jawless vertebrates. Two types of thelodont scales (c,d) from this locality may have belonged to a form resembling *Turinia* (e), known from the Lower Devonian of Scotland. The

scales also resemble those of a thelodont recently described from the Devonian of Australia, *Australolepis seddoni*. Similarly, peculiar shark spines from the locality recall those of *Antarctilamna*, from the Middle Devonian of Antarctica and Australia.

Moreover, large acanthodian spines from Seripona, as well as from several other Lower Devonian localities in Bolivia, display the same superficial ornamentation, with alternating broad and narrow ridges without nodes, as the spines of *Sinacanthus*, a large climatid acanthodian from the Middle Devonian of south China.

Any large-scale biogeographic conclusions would be premature. But at a time when the early history of the Pacific is being vigorously discussed by geophysicists and palaeobiogeographers (Nur, A. & Ben-Avraham, Z. in *Vicariance Biogeography, a Critique*, 341 (Columbia University Press, 1983), the Devonian fishes of South America should provide a valuable tool for estimating Palaeozoic trans-Pacific relationships, particularly since most of them lived very near to the continental shore.

Cell activation

The 'basic' connection

from Walter F. Boron

CHARACTERIZATION of a new biological process almost always includes a description of how it is influenced by changes in pH. In the case of the processes controlled by the enzyme protein kinase C, the tables have been turned; current emphasis is placed on how activation of this kinase affects the pH within the cell (pH_i). Any process that alters pH_i is of potential interest inasmuch as a shift in pH_i could act as a signal to modulate a host of pH-sensitive processes. Activation of protein kinase C is of special interest, because it is believed to mediate the intracellular effects of a wide variety of extracellular signals. On page 371 of this issue Moolenaar *et al.* present evidence that activation of protein kinase C stimulates the plasma membrane Na-H exchanger — which is responsible for the exchange of sodium ions for hydrogen ions across the outer membrane of cells — and thereby leads to an elevation of pH_i in human fibroblasts, HeLa cells and mouse neuroblastoma cells¹. Grinstein *et al.* have reached similar conclusions in experiments on rat thymic lymphocytes². The implication of these data is that the intracellular alkalization induced by the activation of protein kinase C is an important step in the process by which certain extracellular signals elicit their physiological effects.

The Na-H exchanger ultimately affected by protein kinase C is normally involved in the active regulation of pH_i , a house-keeping function performed by all studied animal cells except the erythrocyte. The fundamental acid-base problem faced by these cells is their chronic tendency towards intracellular acidosis, usually caused by the passive influx of acids, such as H^+ , or efflux of bases, such as HCO_3^- , but sometimes caused by the metabolic generation of acid. Uncontrolled falls of pH_i are prevented by ion-transport systems that have the effect of extruding acid from the cell. The invertebrate system appears to exchange external Na^+ and HCO_3^- for internal Cl^- and H^+ , whereas most vertebrate cells use a transporter that exchanges external Na^+ for internal H^+ . Both acid-extrusion mechanisms are ideally suited to their role by being virtually inactive at high pH_i values, and progressively stimulated as pH_i falls below a certain 'threshold'³. This is at least in part due to an intracellular H^+ -binding modifier site, distinct from the site that binds H^+ for transport^{4,5}. The first evidence for modulation of a pH_i regulator was that cyclic AMP stimulates the $Na^+/HCO_3^- - Cl^-/H^+$ exchanger of barnacle muscle⁴. Part of the action of parathyroid hormone on the renal proximal tubule may be due to the inhibition of Na-H exchange by cyclic AMP⁵.

A possible role for Na-H exchange in the

regulation of cell growth by extracellular signals was suggested by experiments in which exposure of quiescent Swiss 3T3 cells to a combination of platelet-derived growth factor (PDGF), vasopressin and insulin, caused a Na^+ -dependent rise in pH_i of about 0.15, as well as a marked stimulation of Na^+ uptake⁷. Subsequently, epidermal growth factor (EGF) was shown to increase pH_i by 0.1–0.2 within ten minutes, but not in the presence of amiloride, an inhibitor of Na-H exchange^{8,9}. Activation of the quiescent cells culminates in cell division several hours later. The notion that an early rise of pH_i plays a role in triggering the cell into division is supported by the observation that the degree of intracellular alkalization induced by growth factors closely parallels the subsequent stimulation of DNA synthesis¹⁰. Thus, the Na-H exchanger, via its effect on pH_i , may be a critical regulator of cell growth.

The cascade of events by which growth factors stimulate Na-H exchange may be as follows: a growth factor, such as EGF¹¹ or PDGF¹², binds at the plasma membrane to a specific receptor (that also has the activity of phosphorylating proteins at tyrosyl residues). A consequence of the binding is the release of Ca^{2+} and increased breakdown of inositol phospholipids. The latter results in the production of diacylglycerol, a potent activator of protein kinase C¹³, which phosphorylates proteins, including the receptor for EGF (see ref. 14), at seryl and threonyl residues. Finally, as indicated by the new data of Moolenaar *et al.*¹, protein kinase C somehow stimulates the Na-H exchanger.

Certain phorbol ester tumour promoters that bear a structural similarity to diacylglycerol are commonly used to stimulate protein kinase C in laboratory investigations. Moolenaar *et al.* show that one such phorbol ester, 12-O-tetradecanoylphorbol-13-acetate (TPA), but not a biologically inactive analogue, causes pH_i to increase by about 0.15 within ten minutes, much as it changes after direct stimulation of fibroblasts by polypeptide growth factors. The TPA-induced increase of pH_i is Na^+ dependent and is blocked by a potent amiloride analogue, indicating that it is caused by stimulation of a Na-H exchanger. Furthermore, TPA does not induce a pH_i increase in fibroblasts that have already been stimulated by PDGF. Inasmuch as TPA bypasses the growth-factor receptor/kinase step of the proposed cascade, a simplistic view would be that stimulation of the Na-H exchanger does not require the release of either Ca^{2+} or diacylglycerol *per se*, but only the activation of protein kinase C. Indeed, the

observations of Moolenaar *et al.* on Na-H exchange, as well as those of others on secretory processes (see ref. 15), indicate that TPA can produce its pharmacological effect without a measurable rise of intracellular Ca^{2+} .

The simplest explanation for the effects of TPA on pH_i , and the one proposed by Moolenaar *et al.*, is that protein kinase C directly phosphorylates the Na-H exchanger. This remains to be established. The kinetic effect of TPA on the Na-H exchanger could be to increase its pH_i threshold — that is to increase the value to which pH_i must rise before the Na-H exchanger shuts off — and/or to increase its sensitivity to acidosis once pH_i falls below the threshold. Moolenaar *et al.* favour the former. This is an attractive possibility, although it is easy to imagine how phosphorylation near the intracellular modifier site could alter either the pH_i threshold or the sensitivity of the Na-H exchanger.

Finally, it is intriguing to speculate on the possible physiological role of the stimulated Na-H exchanger. Most of the experiments on the effects of growth factors on pH_i have been conducted in HCO_3^- -free media. Elsewhere, Moolenaar *et al.* have reported that unstimulated human fibroblasts do not have a detectable HCO_3^- transport system¹⁶. However, L'Allemain *et al.*¹⁰ report that, whereas a functional Na-H exchanger is necessary for stimulating the mitogenesis of Chinese hamster lung fibroblasts that are incubated in HCO_3^- -free media, it is not necessary when the cells are in HCO_3^- -containing media. Is the Na-H exchanger in these hamster cells functionally replaced by a HCO_3^- transport system? Other, more general questions arise. Is a sudden increase of pH_i really necessary to trigger cell growth? Or do growth factors stimulate Na-H exchange for other reasons, such as to enhance the housekeeping ability of the cell to regulate pH_i in anticipation of the increased requirements of the cell on metabolic activation? □

Territory, size and weight gain

SIR — A recent paper by Carpenter *et al.*¹, on territory size and weight gain, has been received with enthusiasm by Diamond². One must share his attitude towards their elegant experimental technique for weighing birds undisturbed in the wild. However, I believe more caution should be exercised with regard to their results and interpretation. Diamond quotes the example of bird WP whose rate of weight gain was measured at three territory sizes and found to be greatest at the intermediate and final size. "The results with WP and other rufous hummingbirds", Diamond says, "reveal that the birds adjust their territory size until they have maximized the rate of weight gain". But WP was in fact the only individual bird observed to have a higher rate of weight gain for an intermediate territory size and even in this case there is no direct evidence that the rate of weight gain achieved was a maximum. The justification for concluding that the birds did maximize their energy input was that in four out of five cases the highest weight gains achieved were on the last day or days of the birds' stay on the study site. Clearly this only demonstrates a level at which birds no longer attempt to increase their net energy input, not that that level is a maximum. The argument for a general "humped" relationship between territory size and weight gain is that some birds showed increases in weight gain with increasing territory size and some with decreasing territory size — a much weaker case than that implied by using the example of WP alone.

Alternative explanations for the observations are possible. For example, suppose that the rate of weight gain is related to the bird's body weight. The observed increase in rate of gain towards the end of each bird's stay is predicted, but is independent of territory size. This would also explain the unusually high rate of weight gain of bird BGR — the bird with the highest initial body weight.

A further problem arises with the proposed adjustment of territory size by "trial and error". Suppose a bird has a sub-optimal energy gain from its initial territory size. Given a bell-shaped relationship between territory size and weight gain, how does the bird decide in which direction to alter its territory size? Even after one alteration made in a random direction the bird still has no good grounds on which to make its next decision.

Apart from the valuable technical innovation, the most important point which comes out of this work is, surely, that the birds do not behave optimally. On arrival at the study site, they do not know and cannot know what the optimum territory is. It depends on many unknown factors, such as nectar production by the flowers and the number and quality of the birds'

neighbours. They spend at least the first few days, if not all of their stay, in territories that are either too large or too small and the best they can do is to try to increase their efficiency as time goes on.

Pigeons, canaries and problem-solving

SIR — I regret that I must question the accuracy of Pastore's¹ recent letter concerning my report of problem-solving behaviour in pigeons². He suggests that I was remiss in not citing his early studies in which a canary was confronted with several Köhler-type problems. He implies that the canary solved both Köhler's one-box problem and Köhler's stacking problems in an "insightful" fashion, but the original reports of this work^{3,4} do not confirm that.

The single canary that Pastore confronted with a variant of the one-box problem required 25 reinforced trials before it could move its box (a cardboard "prism") smoothly to the correct position on the floor of the chamber. So the behaviour that superficially resembled that of Köhler's chimps was, as Pastore originally reported, learned in virtually the same haphazard fashion as the escapes of Thorndike's⁵ cats. Ironically, the performance of the canary was exactly that which Köhler dismissed as mere "trial and error". By no reasonable criteria could the canary's performance be considered "insightful".

On the stacking problem, in which stacking behaviour is also established haphazardly after many reinforced trials, Pastore³ originally reported that "in the crucial trial, when both prism and box were out of position, the canary seemed to be unable to stack them in a meaningful way. Actually, the canary did stack prism and box appropriately in only 10 of 100 trials" (p. 289). No mention is made of success in stacking a larger number of boxes, contrary to Pastore's¹ recent statement. A second canary could not complete even the preliminary stages of the experiment. Praxists and psychologists long ago passed judgment on these modest demonstrations: they are almost universally uncited in the literature relevant to my research.

In contrast, my colleagues and I reported a systematic study with 11 pigeons in which all 3 with relevant training histories solved the box-and-banana problem in a dramatic human-like fashion the first time they were confronted with it. The performances satisfied all of the traditional criteria of "insight": periods of apparent confusion were followed by sudden, rapid, and entirely appropriate performances. By

systematically varying the training histories of other birds, we also determined the possible contributions that a variety of different experiences had made to success in the problem. Finally, we offered a running account of the novel performances in terms of empirically validated principles.

DNA sequence selection by eye

SIR — The recent correspondence concerning various ways of representing DNA sequences^{1,2} prompts me to describe a simple method for finding sequence overlaps by eye. Using the 4,361-nucleotide sequence of the plasmid pBR322 as a test system, it is possible with a little practice to locate a randomly selected sequence of about 100 nucleotides in less than 2 minutes.

The method requires four ballpoint pens of different colours and the sequence (or collection of sequences) with which the test sequence is to be compared is coded as follows. Every time the sequence AG (an arbitrary choice) occurs, the next base is coloured, the colour used depending on the next base again (G green, A blue, C black, and T red). Thus AGCT appears as a red C, AGGG appears as a green G and so forth. This process takes about 10 minutes per kilobase, but it only has to be done once for each new sequence determined.

To locate the test sequence, an AG is selected at random and about ten adjacent downstream bases are written with a sharp pencil on the edge of a piece of paper. The appropriate base adjacent to the G is coloured and the sequence is checked against each occurrence of that coloured letter, on average four times per kilobase.

If two AG sequences are close together on the test sequence, the pattern of two coloured letters separated by a certain number of bases makes searching faster and also highly specific. Such a pattern would only occur at random three times in the entire Epstein-Barr virus sequence.

If the sequence is not found, the complementary strand is searched by locating one or more CT sequences, writing down the ten or so downstream bases on the complementary strand and proceeding as before.

Transformation by the p21^{ras} protein

SIR — Ralph¹ has questioned the validity of certain speculative comments of mine concerning the mechanisms by which p21^{ras} proteins transform mammalian cells. He has obviously misunderstood the point of my remarks.

In my article, I drew an analogy between new findings showing loss of GTPase activity in the transforming protein and the fixation of adenylate cyclase Gs protein in the GTP state after cholera toxin binding. In case it was not made clear in the article, perhaps I should state that there is no evidence of a functional link between the adenylate cyclase system and p21^{ras}, and therefore for a direct role of cyclic AMP regulation in *ras*-mediated transformation. Examples of some of the known effects of cholera toxin on cell physiology and proliferation were mentioned solely to illustrate the profound consequences which result from fixation of the adenylate cyclase G-protein in the GTP form. As stated in my article, which (if any) specific effector systems involve p21^{ras} in signal transduction remains to be established.

The gyroscope test of relativity

SIR — Your account of the "relativity gyroscope experiment"¹ does not go beyond that of Schiff², who proposed that two effects, the geodetic (de Sitter or spin-orbit) and motional (Lense-Thirring or spin-spin) precessions, could be measured separately by the use of at least two gyros in free fall in a perfect polar orbit. An accuracy of 0.3 milliarc-seconds per year is the desired goal. However, there are many other contributions which are well above 0.3 marc s yr⁻¹ (for a review see ref. 3).

The goal of the experimentalists is to make a sphere of fused quartz accurate to one part in 10⁷, but even a perfect sphere is distorted when set spinning, acquiring a quadrupole moment, which for an altitude of 500 miles, will contribute more than 0.3 marc s yr⁻¹ to the gyro drift rate if the spin axis is more than 20 minutes of arc away from either the orbit plane or the perpendicular to the orbit plane⁴.

Second, the Earth's quadrupole moment will contribute an amount of 4 marc s yr⁻¹, more than ten times the desired accuracy, and, more subtly, distorts the satellite orbit so that, in averaging over a polar orbit, one obtains an additional "indirect contribution" of 1.33 marc s yr⁻¹.

Third, the contribution due to the Sun will give rise to a geodetic precession of the gyro (due to interaction of the spin of the gyro with its orbital angular momentum about the Sun), with the relatively

large value of 19.2 marc s yr⁻¹, while the deflection of light from the reference star (Rigel in Orion) can cause an apparent drift of the gyroscope of up to 14.4 marc s yr⁻¹.

The relativity gyro experiment test of general relativity is thus more complex than originally envisaged. Hence, there is a need for other tests of the geodetic and motional precessions, particularly the latter. A promising suggestion in this direction is the proposal of Scully and co-workers^{5,6} to use a ring laser interferometer to test both the geodetic and the motional precessions, which has the attraction that it can be carried out on Earth, while another proposal is to use a Foucault pendulum at the South Pole⁷. Also, the binary pulsar PSR1913+16 may provide a test of the spin-orbit precession and our calculations⁸ predict a precession rate for the pulsar spin axis of 1.23° yr⁻¹, based on the data of Taylor and Weisberg⁹.

Mouse Igx sequence elements in *Drosophila*

SIR — Two sequence elements may be needed for correct transcription of the mouse immunoglobulin α gene. They are: TNATTTGCAT (dc), its inverted and complementary ATGCAAATNA (cd), upstream of the H-chain gene and TGCA⁶CTGTGNCCAG (pd)¹. The same sequences (8 out of 10 base pairs) ATTTGCAT and ATGCAAAT have been found by Parslow *et al.* independently². Sequences related to the above elements were found upstream of all human and mouse α and λ variable region genes and within the mouse heavy-chain enhancer in a homology of 50–100%. The same elements are present in high homology in chicken ovalbumin gene, sea urchin histone gene cluster and in other genes¹. I report here that the elements dc and cd are present upstream of the homoeotic gene *ftz*³ of *Drosophila*.

The element AGGCAAATAC is found upstream the coding region of *ftz* (first

nucleotide position -794)³. This has 78% homology with the cd element ATGCAAATNA. The sequence ATGTTTGCAT is also found upstream of the coding region of *ftz* (first nucleotide -854)³ and shares 78% homology with the dc element TNATTTGCAT. Other sequence elements can also be found upstream or within the *ftz* gene with less homology with the dc, cd or pd 50–67%, but this does not seem to be significant since dc, cd or pd can be found in many genes when homology less than 70% is considered (F. G. Falkner and H. G. Zachau, personal communication).

The dc and cd elements are highly conserved among many genes. Their location within the immunoglobulin genes suggests functional relation¹. The homoeotic gene *ftz* is associated with *Drosophila* development and contains a highly conserved region, the homoeo box, which has been found in other homoeotic genes — *Antp* and *Urb* of *Drosophila* as well as in a wide spectrum of animals. The relationship of conserved sequences needed for transcription to upstream sequences needed for segmentation during development is unknown. It is, of course, possible that the homologies might be chance events, and more information is needed before evolutionary or functional relationships are considered.

FAULKNER AND ZACHAU REPLY — We agree that the occurrence of dc-related elements upstream of genes deserves attention. We quote some examples for that in our previous paper¹ and others in a forthcoming one (F. G. F., E. Neumann and H. G. Z., manuscript in preparation). At this point we would like to mention that a sequence fully homologous to dc was found upstream of all or most histone H2B genes², a point which we had missed previously. In general, we searched sequence libraries for dc at the 89% homology level since at lower levels too many sequences are picked up. But also dc (and pd) related sequences with lesser homology may be interesting if they can be correlated with putative regulatory functions. One example of this which we recently encountered is the finding of the dc and cd related sequences in the regulatory regions upstream of catabolite-sensitive genes of *Escherichia coli*^{3,4}.

Inositol trisphosphate, a novel second messenger in cellular signal transduction

Michael J. Berridge* & Robin F. Irvine†

* AFRC Unit of Insect Neurophysiology and Pharmacology, Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, UK

† Department of Biochemistry, AFRC Institute of Animal Physiology, Babraham, Cambridge CB2 4AT, UK

There has recently been rapid progress in understanding receptors that generate intracellular signals from inositol lipids. One of these lipids, phosphatidylinositol 4,5-bisphosphate, is hydrolysed to diacylglycerol and inositol trisphosphate as part of a signal transduction mechanism for controlling a variety of cellular processes including secretion, metabolism, phototransduction and cell proliferation. Diacylglycerol operates within the plane of the membrane to activate protein kinase C, whereas inositol trisphosphate is released into the cytoplasm to function as a second messenger for mobilizing intracellular calcium.

THE behaviour of all cells from one instant to another is governed by signalling systems that translate external information into a limited repertoire of internal signals, second messengers. Receptors on the cell surface function as molecular antennae, detecting external information (for example, hormones, growth factors, neurotransmitters or light) which is then transduced and amplified into the second messengers which control many cellular processes such as metabolism, secretion, contraction, phototransduction and cell growth. Interest in this field of signal transduction is growing for several reasons, but perhaps not least because an imbalance of second messengers may be responsible for normal cells becoming cancerous.

The signalling system using cyclic AMP as the second messenger may be the best known. Until recently, we knew much less about the nature of the second messengers used by another major signalling pathway that utilizes the inositol lipids as part of a transduction mechanism. Stimulated inositol metabolism was discovered by Hokin and Hokin¹, who showed that the incorporation of ³²P into phospholipids in pancreas was stimulated by acetylcholine. It later became clear that a stimulated catabolism of inositol lipids occurs in many different cells in response to a wide range of external signals²⁻⁴. Durell and co-workers⁵ suggested that this stimulated metabolism may be a part of receptor function, while Michell subsequently proposed that inositol metabolism is concerned with the mode of action of those agonists which raise intracellular calcium⁶. Although this hypothesis is not universally accepted in its entirety^{6,7}, the many coincidences between calcium-mobilizing agonists and stimulated inositol turnover⁸, and many negative 'controls' (that is, receptors which do not mobilize calcium do not stimulate inositol catabolism) has led to a widespread acknowledgement that calcium and inositides are closely linked. It has also become clear that the mobilization of calcium from intracellular stores is an important source of activator calcium following stimulation of many different cells, including oocytes⁹, Swiss 3T3 cells¹⁰, pancreas¹¹, parotid¹², GH₃ pituitary cells¹³, blood platelets¹⁴, insulin-secreting β -cells¹⁵, liver¹⁶ and smooth muscle¹⁷. Thus, there has been a missing link not only between calcium and inositides, but also between the plasma membrane (where the relevant receptors lie) and the internal stores of calcium. Our hypothesis is that inositol trisphosphate (InsP₃) is that missing link.

Formation of inositol trisphosphate

The major metabolic pathways responsible for the formation and degradation of InsP₃ are illustrated in Figs 1 and 2 (for reviews see refs 3, 18). Phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂) is one of the inositol lipids located in the inner leaflet of the plasma membrane (Fig. 1), and is formed by a

two-stage phosphorylation of phosphatidylinositol, which is first phosphorylated at the 4-position of its inositol head group by a specific kinase to form phosphatidylinositol 4-phosphate (PtdIns(4)P); this is in turn further phosphorylated at the 5-position to give PtdIns(4,5)P₂, which is the immediate precursor used by the receptor mechanisms. As well as the two kinases responsible for the stepwise phosphorylation of phosphatidylinositol to PtdIns(4,5)P₂ (Fig. 1), there are corresponding phosphomonoesterases which convert PtdIns(4,5)P₂ back to phosphatidylinositol (Fig. 2) These kinases and phos-

Table 1 Summary of the tissues which respond to external stimuli by a change in the hydrolysis of PtdIns(4,5)P₂

Tissue	Stimulus
Rabbit iris smooth muscle	Acetylcholine ^{20,21*}
Brain	Acetylcholine ^{50*}
Parotid	Acetylcholine ^{50*,105*,106*} , substance p ^{50*}

Neuroblastoma-glioma hybrid NG108-15	Bradykinin ¹³⁵
Photoreceptors	Photons ^{42*,43}
Sea urchin eggs	Spermatozoa ⁸⁵

PtdIns(4,5)P₂ hydrolysis was usually measured by following changes in the distribution of ³H-inositol or ³²P.

* Papers describing increases in the formation of labelled inositol trisphosphate (likely to be a mixture of the two isomers¹⁹). For more extensive lists of tissues where inositol turnover in general (rather than PtdIns(4,5)P₂ in particular) is stimulated, see refs 2, 8, 22.

Fig. 1 The proposed role of inositol trisphosphate as an intracellular second messenger. Agonists bind to external receptors (R_1) to stimulate the hydrolysis of $\text{PtdIns}(4,5)\text{P}_2$ by a phosphodiesterase (PDE) to form diacylglycerol (DG) and InsP_3 . The latter may have a number of second messenger functions one of which is to bind to a specific receptor (R_2) on the endoplasmic reticulum to release calcium. The action of InsP_3 is curtailed by an inositol trisphosphatase which removes a phosphate from the 5-position to form InsP_2 . The enzymatic pathways responsible for resynthesising phosphatidylinositol from diacylglycerol and InsP_3 are shown in Fig. 2. *a*, Phosphatidylinositol kinase; *b*, $\text{PtdIns}(4)\text{P}$ kinase; PDE, $\text{PtdIns}(4,5)\text{P}_2$ phosphodiesterase.

phosphoesterases constitute two linked phosphatidylinositol/ $\text{PtdIns}(4,5)\text{P}_2$ futile cycles whereby phosphates are constantly being added to and removed from the 4- and 5-positions of the inositol head group. Such futile cycles are metabolically expensive, which may explain why the operation of this signal transduction mechanism is rapidly curtailed by metabolic inhibitors⁴. Occupation of a receptor by an agonist diverts $\text{PtdIns}(4,5)\text{P}_2$ out of the futile cycle towards a phosphodiesterase (phospholipase C), by which it is cleaved into *sn*-1,2-diacylglycerol and InsP_2 (Figs 1, 2).

In passing, it should be noted that two naturally occurring isomers of inositol trisphosphate have been identified, D-*myo*-inositol 1,4,5-trisphosphate and D- or L-*myo*-inositol 1,3,4-trisphosphate¹⁹. In most of the studies summarized in Table 1, where increases in inositol trisphosphate following cell stimulation have been reported, the measurements probably include both isomers. Because the 1,3,4-isomer has only just been described and its function is unknown, we have concentrated our attention on the 1,4,5-isomer, which we abbreviate as InsP_3 .

Stimulated catabolism of one of the polyphosphoinositides was first detected by Durell *et al.*⁵, but other workers later documented in detail the phosphodiesterase cleavage of $\text{PtdIns}(4,5)\text{P}_2$ in iris smooth muscle to form InsP_3 (refs 20, 21). At first, however, this reaction was thought to be a consequence of the calcium signal in the stimulated tissue, rather than its cause. A crucial advance which changed our concept of inositide metabolism and its function, was the discovery that, in hepatocytes stimulated by vasopressin, decreases in $\text{PtdIns}(4,5)\text{P}_2$ precede changes in phosphatidylinositol and are largely independent of external calcium²². The primary receptor-stimulated event is probably the hydrolysis of $\text{PtdIns}(4,5)\text{P}_2$ to yield *sn*-1,2-diacylglycerol (as does phosphodiesterase hydrolysis of any glycerophospholipid) and—uniquely to $\text{PtdIns}(4,5)\text{P}_2$ — InsP_3 as a water-soluble product^{3,4,22}. There are now many studies which support the notion that this hydrolysis of $\text{PtdIns}(4,5)\text{P}_2$ is a common response by many different kinds of cells to a wide variety of external stimuli (Table 1). The demonstration that the formation of InsP_3 precedes that of inositol monophosphate (the expected product of phosphatidylinositol hydrolysis) in *Calliphora* salivary glands^{23,24} and clonal GH₃ pituitary cells^{25–27} provides additional evidence that $\text{PtdIns}(4,5)\text{P}_2$ is the primary substrate for the receptor. Most importantly, InsP_3 formation in *Calliphora* salivary glands is

stimulated by serotonin with no apparent lag, whereas the onset of the calcium-dependent physiological response is delayed by at least 1 s. This led to the suggestion that InsP_3 is the second messenger for calcium mobilization^{23,24}. Increases in InsP_3 following cell stimulation also precede physiological responses in liver²⁸ and GH₃ cells²⁹, thus confirming that InsP_3 formation is fast enough for it to function as a second messenger.

One unsolved problem in the formation of InsP_3 and diacylglycerol is that of how receptors are coupled to the $\text{PtdIns}(4,5)\text{P}_2$ phosphodiesterase (Fig. 1). A recent report that vasopressin can stimulate the breakdown of $\text{PtdIns}(4,5)\text{P}_2$ in isolated membranes³⁰ may help to elucidate the transduction mechanism. Agonists may induce a conformational change in the receptor, which in turn perturbs the membrane sufficiently to make $\text{PtdIns}(4,5)\text{P}_2$ accessible to the phosphodiesterase³¹. $\text{PtdIns}(4,5)\text{P}_2$ phosphodiesterase may also be controlled by coupling of receptors to the enzyme through a GTP-binding protein as in the mechanism used to link receptors to adenylate cyclase^{32,33}.

The first indications that a GTP-binding protein may function in signal transduction for calcium-mobilizing receptors were reports that GTP reduces the affinity of noradrenaline for α_1 -receptors³⁴ and that of carbachol for muscarinic receptors³⁵. In adrenoreceptors, pertussis toxin reduces the modulatory effect of GTP on α_2 -receptors, which act by inhibiting adenylate cyclase, but has no effect on the calcium-mobilizing α_1 -receptors, suggesting that these two receptor mechanisms are regulated by different GTP-binding proteins³⁶.

A more direct link has emerged from studies on permeabilized blood platelets, where either GTP or its non-hydrolysable analogues GTP γ S or GppNHP enhances the calcium sensitivity of the secretory mechanism³⁷, apparently by stimulating the formation of diacylglycerol³⁸. The stimulatory effect of guanine nucleotides introduced into various intact cells can probably be reinterpreted on the basis that they stimulate the hydrolysis of inositol lipids³⁷. For example, stimulation of mast cell secretion by non-hydrolysable GTP analogues³² may result from stimulation of the normal receptor mechanism³⁷. Likewise, the ability of GTP γ S to excite *Limulus* photoreceptors may also depend on the activation of a GTP-binding protein^{39,40}. Such a protein has been identified in squid photoreceptors⁴¹, where light stimulates the turnover of $\text{PtdIns}(4)\text{P}$ and $\text{PtdIns}(4,5)\text{P}_2$ (refs 42, 43). Finally, the *ras* gene product, p 21, which is a membrane-bound

for the store are the mitochondria and the endoplasmic reticulum. These can be distinguished from each other by loading with calcium at different concentrations or by using various metabolic inhibitors. When calcium is buffered at 180 nM, permeabilized liver cells accumulate calcium in a non-mitochondrial pool which is sensitive to InsP_3 (ref. 58). Conversely, there is no release when cells are allowed to accumulate calcium in a mitochondrial pool^{58,59,66}. Inhibition of mitochondrial function by removing metabolic substrates or by adding inhibitors (antimycin, oligomycin, Ruthenium red) has no effect on the ability of InsP_3 to release calcium from the ATP-dependent vesicular pool^{57,59,62,67}. Thus, the InsP_3 -sensitive release site is probably the endoplasmic reticulum, not the mitochondria.

This conclusion is supported by cell fractionation experiments, which show that InsP_3 can release calcium from microsomes but not from isolated mitochondria^{65,69}. After further fractionation of pancreatic microsomes, InsP_3 -sensitive release is localized predominantly in those vesicles containing markers for the endoplasmic reticulum rather than the plasma membrane⁶⁹. Insulinoma microsomes do not respond to a second challenge with InsP_3 (ref. 65), which can probably be explained by vesicle heterogeneity⁶⁰. When InsP_3 is first added, calcium is chased out of the InsP_3 -sensitive vesicles only to be mopped up by those which are insensitive⁶⁰. This heterogeneity suggests that, within the intact cell, only a part of the endoplasmic reticulum, perhaps that lying close to the plasma membrane, may be sensitive to InsP_3 . Changes in intracellular calcium in response to agonists may, therefore, not be uniform, but may be localized in specific regions depending on the juxtaposition of surface receptors and intracellular calcium stores¹⁷. An analogous arrangement may occur in cardiac muscle, where calcium is thought to be taken up over the whole surface of the sarcoplasmic reticulum but to be released only from the terminal cisternae close to the T-tubules⁷⁰.

Previous studies with intact liver suggested that the hormone-dependent mobilization of calcium involves an amplification step, for more than 10 calcium ions are released for each molecule of $\text{PtdIns}(4,5)\text{P}_2$ hydrolysed by the receptor mechanism⁷¹. One amplification step probably resides at the level of the endoplasmic reticulum; for example, using data from permeabilized liver cells⁵⁹, we calculate that each InsP_3 molecule releases at least 20 calcium ions. Just how this calcium is released from the endoplasmic reticulum is unknown, but current evidence favours the view that InsP_3 acts by stimulating calcium efflux (as shown in Fig. 1) rather than by inhibiting calcium uptake. When the latter is blocked completely, either by adding vanadate or by removing ATP, there is a gradual release of calcium which is very much slower than that obtained by adding InsP_3 (ref. 67). Furthermore, the calcium mobilizing effect of InsP_3 was greatly enhanced when calcium uptake was blocked. The ability of InsP_3 to release calcium from the endoplasmic reticulum was unaffected by nifedipine (5 μM), verapamil (10 μM), cobalt (100 μM), dantrolene (30 μM) or Ruthenium red (20 μM)⁶⁶.

The specificity of the putative InsP_3 receptor on the endoplasmic reticulum (R_2 in Fig. 1) has been analysed by testing a range of inositol phosphates and closely related compounds (Table 2). It is of particular interest that InsP_2 , formed when InsP_3 is hydrolysed⁴⁹ by inositol 1,4,5-trisphosphate 5-phosphatase (Fig. 1), has no effect. The InsP_3 -binding site on that enzyme is apparently distinct from the receptor on the endoplasmic reticulum, because 2,3-diphosphoglyceric acid, which blocks the trisphosphatase⁴⁹, has no effect on the ability of InsP_3 to release calcium⁶⁴. A common feature of the four inositol phosphates which can release calcium^{61,64} (Table 2) is that they all have the pair of vicinal phosphates at the 4- and 5-positions (Fig. 1). These two phosphates appear to be essential for full activity (ability to release calcium), whereas the remaining phosphate, at the 1-position, seems to enhance the affinity of InsP_3 for its receptor. Moving this phosphate from the 1- to the 2-position causes some reduction of affinity, and removing it altogether causes a dramatic reduction in the ability of the molecule to

Table 2 Specificity of InsP_3 -sensitive calcium mobilization

Inactive compounds	Concentrations tested (μM)
2,3-Diphosphoglycerate ⁶⁴	2,000
Fructose 1,6-bisphosphate ⁶³	10
<i>myo</i> -Inositol ^{57,58,63,65,66}	2.5–100
Inositol 1-phosphate ^{57,58,65}	5–10
Inositol 2-phosphate ^{63,66,67}	7.5–10
Inositol 1,2-cyclic phosphate ^{57,58,63}	5–10
Inositol 1,4-bisphosphate ^{57,58,63–65,67}	1–50

Active compounds	Concentration giving half-maximal release (μM)	Tissue
Inositol 1,4,5-trisphosphate	0.4	Rat pancreas acinar cells ⁵⁷
Inositol 1,4,5-trisphosphate	0.1	Rat hepatocytes ⁵⁹
Inositol 1,4,5-trisphosphate	0.2	Guinea pig hepatocytes ⁵⁸
Inositol 1,4,5-trisphosphate	0.3	Swiss 3T3 ^{63,64}
Inositol 1,4,5-trisphosphate	0.5	Rat insulinoma ⁶⁶
Inositol 1,4,5-trisphosphate	0.7	Porcine artery cells ⁶⁸
Inositol 1,4,5-trisphosphate	0.75	Human neutrophils ⁶⁷
Inositol 1,4,5-trisphosphate	0.8	Macrophages ¹³⁹
Inositol 1,4,5-trisphosphate	1.0	GH ₃ cells ⁶²
Inositol 1,4,5-trisphosphate	0.50	Rat liver microsomes ⁶⁰
Inositol 1,4,5-trisphosphate	3.0	Insulinoma microsomes ⁶⁵

Inositol 4,5-bisphosphate	~50	Guinea pig hepatocytes ⁶¹

mobilize calcium (Table 2). The most effective molecule tested so far is one of the naturally occurring isomers¹⁹, with the three phosphates in a D-1,4,5-configuration.

The rate at which InsP_3 is formed after cell stimulation^{23,24,28,29} is fast enough for it to be the messenger causing calcium mobilization, but the concentration which it can reach in stimulated tissues is at present unknown. Rough estimates based on the $\text{PtdIns}(4,5)\text{P}_2$ content of tissues⁵⁷ and direct measurements of labelled InsP_3 (refs 28, 58, 72) give values in the micromolar range, which are within the levels active on permeabilized cells (Table 2). These measurements, however, all rely on isotopic techniques where the problems of pool equilibration and the existence of two isomers make accurate estimates impossible.

Phototransduction

Photoreceptors function as transducers by converting the energy of light into the electrical signals that convey visual information to the brain. A gap in our knowledge of phototransduction is the link between photon capture by rhodopsin, and the change in ion permeability that initiates electrical activity. The need for a second messenger in phototransduction is highlighted by the fact that a single photon can open approximately 1,000 sodium channels in *Limulus* photoreceptors³. That InsP_3 may be such a link in phototransduction^{42,73} is borne out by evidence that light causes a decrease^{42,43} in the amount of ³H-inositol in the precursor $\text{PtdIns}(4,5)\text{P}_2$, with a corresponding increase in the amount of labelled InsP_3 (ref. 42). Octopus photoreceptors possess a protein whose GTP binding and hydrolysis functions are sensitive to light⁴¹. As described earlier (Fig. 1), this GTP-binding protein may be responsible for coupling activated receptors (in this case bleached rhodopsin) to the $\text{PtdIns}(4,5)\text{P}_2$ phosphodiesterase which generates InsP_3 .

Fig. 4 The proposed role of diacylglycerol and InsP_3 as intracellular second messengers in regulating cell proliferation. Oncogenes appear to code for various aspects of the signal pathway such as growth factors (*sis*) and the kinases (*src* and *ros*) responsible for forming the substrate ($\text{PtdIns}(4,5)\text{P}_2$) used by the receptor mechanism. The *erb-B* gene codes for a truncated EGF receptor reported to stimulate phosphatidylinositol turnover by some workers^{87,137} but not by others¹³⁸. The *ras* gene product may function to couple receptors to underlying transduction mechanisms such as the $\text{PtdIns}(4,5)\text{P}_2$ phosphodiesterase (PDE). Diacylglycerol apparently acts by raising pH , whereas InsP_3 mobilizes intracellular calcium. 1, Phosphatidylinositol; 2, $\text{PtdIns}(4)\text{P}$; 3, $\text{PtdIns}(4,5)\text{P}_2$.

When injected into the ventral photoreceptors of *Limulus*, InsP_3 induces electrical events which are identical with those produced normally by light^{42,73}. InsP_3 stimulates an inward current, carried mainly by sodium ions, which has a reversal potential identical with that induced by light. As well as functioning as a second messenger in phototransduction, InsP_3 may also be responsible for the process of adaptation^{42,73}. Injection of InsP_3 into photoreceptors reduces their responsiveness to subsequent flashes of light. Conversely, a flash of light causes a reduction in the responses induced by repetitive injections of InsP_3 (ref. 42). As an increase in intracellular calcium has been implicated in adaptation⁷⁴, it is reasonable to suppose that some of the actions of InsP_3 in photoreceptors may be mediated by mobilizing calcium from internal stores. It remains to be seen whether or not InsP_3 is involved in vertebrate photoreceptors.

Cell growth and oncogenes

The discovery of InsP_3 as an intracellular second messenger may contribute to our understanding of those aspects of cell growth and development that depend on the mobilization of calcium from intracellular stores. It has been known for some time that growth factors cause changes in inositol lipid metabolism⁷⁵, but the link between these events at the plasma membrane and the onset of cell proliferation has not been understood. There is now much support for the proposal that both diacylglycerol and InsP_3 may function as second messengers controlling the two major ionic events implicated in cell proliferation (Fig. 4). Diacylglycerol acts within the plane of the membrane to stimulate protein kinase C⁵⁶, which is probably the site of action of the tumour-promoting phorbol esters⁷⁶. As the phorbol esters can activate the Na^+/H^+ exchange carrier^{77,78}, it has been proposed that diacylglycerol may act in a similar way to increase cytoplasmic pH (refs 4, 63). Such an increase in pH is a characteristic feature of the action of growth factors and is thought to have an important role in stimulating cell growth⁷⁹⁻⁸¹.

Calcium has long been implicated in cell proliferation^{82,83}. The increase in intracellular calcium which occurs when cells are fertilized⁹ or stimulated with growth factors^{10,84} may depend on the hydrolysis of $\text{PtdIns}(4,5)\text{P}_2$ to form InsP_3 , which then releases calcium from intracellular stores. The large increase in polyphosphoinositide metabolism in sea urchin eggs following fertilization has been implicated in calcium mobilization⁸⁵. Direct evidence for the involvement of InsP_3 is provided by the observations that injection of InsP_3 (but not InsP_2) triggers some of the initial events of the fertilization process (elevation of the fertilization membrane) in sea urchin⁸⁶ and starfish oocytes (M.J.B. and L. Meijer, unpublished observations). The action of growth factors (platelet-derived growth factor (PDGF), bombesin and vasopressin) on Swiss 3T3 cells results in an increased formation of diacylglycerol⁸⁷ and InsP_3 (refs 63, 88). The latter is likely to function as a second messenger to mediate the calcium-mobilizing action of growth factors⁸⁹, as it can release calcium from permeabilized Swiss 3T3 cells^{63,64}. Thus, the hydrolysis of $\text{PtdIns}(4,5)\text{P}_2$ induced by growth factors results in the activation of two signal pathways which may regulate

two key ionic events responsible for cell proliferation (Fig. 4). The increase in pH may be controlled through diacylglycerol, and the level of calcium by InsP_3 .

The enzymatic reactions associated with this bifurcating signal pathway based on the inositol lipids may represent the sites of action of certain oncogenes (Fig. 4)⁹⁰⁻⁹². The *sis* oncogene is responsible for producing PDGF^{93,94}, known to stimulate inositol lipid metabolism^{63,87}. The *erb-B* gene codes for a truncated EGF receptor⁹⁵. (EGF stimulates an immediate increase in cytoplasmic free calcium in fibroblasts^{10,84}.) Proteins encoded by the *src* and *ros* oncogenes may function as inositol lipid kinases^{90,91} to convert phosphatidylinositol into the $\text{PtdIns}(4,5)\text{P}_2$ used by the receptor mechanism (Fig. 4). It is reasonable to speculate that other oncogenes, whose functions are still unknown, may code for enzymes concerned with the remaining steps of this bifurcating signal pathway⁹². A particularly intriguing possibility is that the activated *ras* gene may transform cells by causing an uncontrolled stimulation of $\text{PtdIns}(4,5)\text{P}_2$ phosphodiesterase (Fig. 4). The normal *ras* gene can both bind and hydrolyse GTP, but on activation by a point mutation at codon 12, the resulting oncogenic protein can still bind GTP⁴⁵, although its ability to hydrolyse this nucleotide is severely impaired^{46,47}. If *ras* does play a part in this receptor mechanism, the loss of GTPase activity means that the oncogenic protein would continue to activate the formation of InsP_3 and diacylglycerol in an uncontrolled way independently of growth factors (Fig. 4).

Most of the oncogenes discovered so far have been identified through viral transformation or transfection assays and are likely to be dominant (drive the signal pathways forward by activating positive steps such as the formation of second messengers). It is conceivable, however, that there may be a set of recessive oncogenes which code for enzymes responsible for inhibitory aspects of the signal pathways such as second messenger removal. The potential targets for both dominant and recessive oncogenes are described elsewhere⁹².

Early development

Ionic currents flowing through oocytes may be responsible for segregating cytoplasmic components to establish an anterior-posterior axis during early development^{96,97}. A calcium-dependent chloride current entering the animal pole has been detected in *Xenopus* oocytes using an extracellular vibrating electrode⁹⁷. Muscarinic receptors, which are concentrated around the animal pole, respond to acetylcholine by inducing a membrane depolarization resulting from the opening of chloride channels^{98,99} themselves regulated by calcium, which is apparently released from intracellular stores by InsP_3 (ref. 100). Injection of eggs with InsP_3 results in an electrophysiological response similar to that normally induced by acetylcholine¹⁰⁰. Even in the absence of acetylcholine, eggs often display spontaneous fluctuations in chloride conductance⁹⁸ which probably account for the chloride current that enters the animal pole. These spontaneous fluctuations may result from the transient accumulation in the animal pole of the same 'channel gating substance'

normally released by acetylcholine⁹⁸ and which could well be InsP_3 . Therefore, a localized accumulation of calcium released by InsP_3 at the animal pole may be responsible for the large influx of chloride at this point. InsP_3 could thus have an important role in early development to establish an egg axis by segregating cytoplasmic components through localized calcium gradients and electric fields.

Calcium entry

In the initial seconds or minutes of cell activation by a number of agonists, the best demonstrated function of InsP_3 as a second messenger is the mobilization of calcium from intracellular stores, particularly the endoplasmic reticulum. If, however, a tissue is to maintain an elevated calcium level, some modification of plasma membrane calcium transport is necessary because of the limited size of the intracellular calcium stores. Whether or not InsP_3 is directly involved is not known, but elevated intracellular levels of calcium could be maintained by inhibition of the calcium pump on the plasma membrane^{101,102} by some mechanism regulated by changes in the level of $\text{PtdIns}(4,5)\text{P}_2$ (ref. 7). The $\text{PtdIns}(4,5)\text{P}_2$ used to generate InsP_3 is an integral part of the bilayer, where it may regulate a number of membrane properties in addition to controlling the calcium pump. The level of $\text{PtdIns}(4,5)\text{P}_2$ may regulate membrane fluidity¹⁰³ or the anchoring and transfer of proteins across the bilayer¹⁰⁴. So, as $\text{PtdIns}(4,5)\text{P}_2$ is consumed to generate second messengers, there may be localized perturbations in the bilayer which alter a number of membrane properties.

Inositol 1,3,4-trisphosphate

In several tissues, InsP_3 levels elevated in response to agonists are prolonged over many minutes^{28,58,105,106}, but a complicating factor in measuring InsP_3 levels is that the predominant inositol trisphosphate may not always be D-inositol(1,4,5)trisphosphate but, rather, D- or L-inositol(1,3,4)trisphosphate¹⁹. The origin and function of this is unknown, because the evidence for its existence comes from radiolabelling studies with ³H- or ¹⁴C-labelled inositol, its abundance in mass terms compared with the 1,4,5-isomer is also unknown. The occurrence of inositol(1,3,4)trisphosphate is therefore a further complication in assessing the rate and extent of InsP_3 accumulation. However, there is also a possibility that inositol(1,3,4)trisphosphate has messenger functions of its own and represents an entirely new facet of inositol function¹⁹. For example, hyperstimulation of the parotid via the cholinergic parasympathetic pathway, which results in a large accumulation of inositol(1,3,4)trisphosphate¹⁹, also stimulates DNA synthesis¹⁰⁷. It is also significant that treatment of cells with 5–20 mM lithium, which enhances the formation of inositol trisphosphate^{27,28,72} (much of which is likely to be the 1,3,4-isomer), is a potent growth stimulus in lymphocytes¹⁰⁸ and mammary¹⁰⁹ and kidney epithelial cells¹¹⁰. Although the 1,4,5-isomer seems to have more immediate effects, for example, calcium mobilization, the 1,3,4-isomer may contribute to longer-term responses, such as the onset of proliferation.

Second-messenger interactions

An important aspect of the bifurcating receptor mechanism which utilizes InsP_3 and diacylglycerol as second messengers is that the two limbs of the signal pathway may sometimes interact with each other synergistically⁵⁶, although an inhibitory effect of protein kinase C on calcium transport has also been reported¹¹¹. One explanation for the synergistic interactions is that the diacylglycerol-sensitive pathway may alter the sensitivity of the calcium pathway. For example, activation of protein kinase C by a phorbol ester results in a large increase in the calcium sensitivity of secretion in blood platelets¹¹² and adrenal medulla¹¹³. Some cellular processes, such as shape change and secretion in blood platelets, can be activated through the C-kinase pathway without a change in the resting level of calcium¹¹⁴, but a more effective stimulus is provided when both pathways act in concert^{56,112,114,115}. Another important interac-

tion is the finding that stimulation of the protein kinase C pathway can greatly enhance the formation of $\text{PtdIns}(4)\text{P}$ and $\text{PtdIns}(4,5)\text{P}_2$ (refs 116, 117). Diacylglycerol could thus function as a positive feedback signal to increase the formation of the $\text{PtdIns}(4,5)\text{P}_2$ required by the receptor mechanism^{116,117}.

Interactions between the cyclic nucleotide and inositol pathways are a relatively unexplored but potentially exciting area. In platelets, for example, cyclic AMP has a marked inhibitory effect on inositol lipid breakdown⁵⁶ (generally interpreted as an inhibition of the phosphodiesterase, but equally likely to be an effect on the kinases or phosphomonoesterases which control $\text{PtdIns}(4,5)\text{P}_2$ levels (Fig. 2)). Reciprocal effects of phorbol esters (presumably acting as diacylglycerol analogues) on the sensitivity of receptors which activate adenylate cyclase have also been reported^{118,119}.

The identification of InsP_3 as a second messenger raises far more questions than it answers. It is clear, however, that the bifurcating signal transduction system of inositol metabolism is used by a wide variety of agonists as a uniquely flexible signalling system. A key role for InsP_3 is to mobilize calcium, but its overall metabolic properties place it in a central position to carry out additional second messenger functions. The extent of its influence is evident from the growing list of tissues in which InsP_3 is a second messenger.

Note added in proof: In contrast to the lack of any effect of pertussis toxin on renal calcium-mobilizing receptors⁵⁰, this toxin inhibits GTP-dependent histamine release in mast cells¹⁴⁰.

ARTICLES

Water column dissolution of aragonite in the Pacific Ocean

Robert H. Byrne*, James G. Acker*, Peter R. Betzer*, Richard A. Feely† & Marion H. Cates‡

 † Pacific Marine Environmental Laboratory, NOAA 7600 Sand Point Way NE, Seattle, Washington 98115, USA
 ‡ Honeywell Inc., Mil-Av Division 13350 US Highway 19S, St Petersburg, Florida 33546, USA

Pelagic pteropods are an important component of the oceanic CO₂ system. Their shells appear to be a principal source of excess alkalinity in the upper water column of the North Pacific Ocean. Dissolution of aragonite must therefore be taken account of in generating models of the oceanic CO₂ system and is also an important cause of sample loss from long-term sediment traps deployed in undersaturated seawater.

MARINE aragonitic detritus is an important component of the oceanic CO₂ system and may constitute worldwide about one half the calcium carbonate (CaCO₃) detritus settling to the ocean floor¹; in some areas of the Pacific Ocean it appears to constitute substantially more than half the total CaCO₃ flux in the upper ocean². Aragonite dissolution provides a means of

explaining alkalinity anomalies in the upper ocean^{2,3} and, in addition, a means of balancing the oceanic CaCO₃ mass budget^{1,4}. Aragonite may be especially important in the short-term buffering of fossil fuel CO₂ injected into the ocean⁵.

The importance of aragonite in the oceans is largely attributable to its rapid dissolution kinetics compared with calcite.

Table 1 Aragonite dissolution rates

$\Omega_{\text{calcite}}^*$	Keir†	Morse <i>et al.</i> †	Eq. (8)†	Eq. (7)‡
1.50	0.09	0.36	0.30	0.46
1.30	0.9	1.9	1.7	1.6
1.15	3.0	4.2	4.2	3.5
1.00	7.5	8.1	8.2	6.6
0.85	16	14	15	12

0.65	38	25 (34)§	27	22
0.55	56	33 (65)§	36	30

Rates (% d⁻¹) predicted by Morse *et al.*⁶, Keir⁷ and this work as a function of saturation state at 5 °C, 34.03‰ salinity and pressures of 60–760 atm. In this analysis we have used the properties of a seawater sample collected at 26° N, 165° E in the North Pacific Ocean.

* Ω_{calcite} calculated using the equations and procedures in Millero¹¹.

† $\rho = 1.78$.

‡ $\rho = 2.05$.

§ The higher dissolution rates shown in parentheses calculated using equation (11).

Consequently, these kinetics have received considerable attention recently. Substantial differences exist between results from careful laboratory investigations^{6,7} and *in situ* analyses^{8,9}; *in situ* aragonite dissolution rate determinations are more than an order of magnitude smaller than predictions based on laboratory analyses. These differences are a major concern in assessing the behaviour of aragonite in the oceans. We have performed a large number of dissolution rate determinations at sea, using freshly collected aragonitic particulates in an attempt to resolve the discrepancy. Our methods are only a small step removed from *in situ* analyses and incorporate advantageous features of laboratory methodology.

Analytical techniques

Our analyses were conducted aboard the RV *Discoverer*, along 165° E in the North Pacific Ocean (station locations and hydrographic data provided in Feely *et al.*¹⁰). Our pteropod samples were collected using free-drifting sediment traps at depths between 100 and 2,200 m. Use of large area (0.66 m²) traps allowed short (~24 h) collection periods and collection of intact pteropod shells with surface chemistries presumably quite similar to those of pteropods settling through the water column. The seawater used in our dissolution analyses was collected at the sediment trap stations along our transect². These samples were generally collected near 2,000 m and were characterized with respect to total CO₂, carbonate alkalinity and pH, as described previously¹⁰.

Our experiments were conducted by examining the dissolution of intact pteropod shells devoid of internal organic matter. In general, individual pteropods were used in each of our 80 experiments. Pteropods were housed in glass-plastic sample vials inside thermostated high-pressure vessels and were gently oscillated at 7 cycles min⁻¹ for the duration of each experiment. Each dissolution experiment was conducted at 5 °C and at pressures near 375 atm; extent of dissolution was monitored by measuring the seawater pH in the sample vials before and after each experiment. The pH changes induced by CaCO₃(s) dissolution

were generally quite small (0.03 ≤ pH ≤ 0.20). In order to maximize the signal-to-noise ratio, our seawater sample volumes were small (~9 ml) and pH was measured using electrodes (Ross-type reference—Orion Research) substantially free of drift in the course of thermal cycling. The total CaCO₃ dissolved in each experiment was determined using the initial alkalinity, pH and total CO₂ characteristics of our seawater samples¹⁰ and by calculating the alkalinity change (twice the change in total CO₂)

Fig. 1 The solubility behaviour of aragonite obtained in various investigations as a function of equilibration time¹⁸. The parameter $\rho = K'_{\text{spA}}/K'_{\text{spC}}$ provides a direct comparison of K'_{spC} , the solubility product of calcite obtained by Ingle *et al.*²⁰ (35‰ salinity, 25 °C) and K'_{spA} , values (35‰ salinity, 25 °C) obtained by: ○, Plath¹⁶; △, Berner¹⁵; □, MacIntyre¹⁷; ●, Morse *et al.*¹⁸. K'_{spC} values obtained in seawater at 25 °C and 35‰ salinity^{14-18,26} agree to within 5%. Consequently ρ is not significantly altered by alternative choices of K'_{spC} . Whereas the minimum value of ρ is reasonably well established, upper-bound values of ρ , appropriate to natural aragonitic particulates undergoing dissolution, are not well defined.

necessary to produce the observed change in pH. The equations and formation constants used in our calculations follow Millero¹¹ and Feely *et al.*¹⁰. Subsequent measurements of sample (pteropod) masses on laboratory microbalances permitted the result of each experiment to be expressed in terms of a % weight loss.

A potential liability encountered in the use of fresh pteropod shells is occasional evidence of bacterial respiration during dissolution experiments. We found an effective remedy for this possibility in the addition of Hg(II) to the seawater samples. Our seawater media were 2×10^{-5} M in Hg(II). Hg(II) has a very substantial affinity for halide ions, so Hg²⁺ is not readily available for interaction with carbonate surfaces. HgCl₄²⁻ substantially dominates the speciation scheme of Hg(II) in seawater¹² and, in our media, free Hg²⁺ concentrations are ~10⁻¹⁹ M.

Detailed laboratory experiments^{6,7,13} have shown that carbonate dissolution rates in seawater generally can be well described by the following expression

$$R = k(1 - \Omega)^n \quad (2)$$

where R is the dissolution rate (% per day), k has the dimensions % per day, n is the reaction order and Ω is the degree of saturation calculated as

$$\Omega = \frac{m_{\text{Ca}} m_{\text{CO}_3}}{K'_{\text{spA}}} \quad (3)$$

where m_{Ca} and m_{CO_3} are total Ca²⁺ and CO₃²⁻ concentrations in mol kg⁻¹ seawater, and K'_{spA} is the temperature, pressure and salinity-dependent apparent solubility product of aragonite in seawater. The cumulative % dissolution in each of our experiments was modelled using the following integral form of equation (2):

$$D = \int_0^t R dt = k \int_0^t \left[1 - \frac{m_{\text{Ca}} m_{\text{CO}_3}}{K'_{\text{spA}}} \right]^n dt \quad (4)$$

Dissolution times in these experiments ranged between one hour and approximately one day. The integrations were performed numerically by dividing the total dissolution time, t , in each experiment, into a large number of segments. Our analyses indicated that dissolution segments ≤ 1 min produced identical model predictions.

Fig. 2 The cumulative % dissolution of pteropods settling at a mid-range rate, 1.4 cm s^{-1} , at two of our station locations in the North Pacific Ocean. Significant dissolution begins at shallow depths at the northernmost station (50°N , 167°E). At 35°N , 165°E dissolution becomes appreciable below 1,000 m. As the influence of dissolution on settling rate is not considered, the cumulative dissolution shown here should be considered as a lower-bound estimate.

Equation (4) was applied here to each of our 80 dissolution experiments. In each analysis a set of parameters (k , K'_{spA} and n) was chosen and held constant. This process generated a value, $D(\text{predicted})$, for each of our experiments. $D(\text{predicted})$ was then compared with $D(\text{observed})$ and the difference was used to generate a residual, ϕ . The quality of a given set of parameters (k , K'_{spA} and n) was evaluated by examining the residual sum of squares generated by modelling the entire 80 experiment data set:

$$\text{residual sum of squares} = \sum_{i=1}^{80} \phi_i^2 \quad (5)$$

According to this process, the residual sum of squares was examined as a function of k , K'_{spA} and n . Our choices of K'_{spA} were constrained by the results obtained in a variety of direct aragonite solubility determinations¹⁴⁻¹⁸. An unusual feature of aragonite solubility relative to that of calcite is the long equilibrium time necessary for attainment of true equilibrium. Morse *et al.*¹⁸ demonstrated that where the aragonite solubility products obtained in various investigations are ordered with respect to equilibration time, a monotonic decrease is observed over a period of weeks (Fig. 1). This behaviour appears to reflect slow variation in the surface chemistry of aragonite¹⁹ and indicates that K'_{spA} appropriate to naturally occurring aragonitic particulates may assume values $\geq 6.65 \times 10^{-7} \text{ (mol}^2 \text{ kg}^{-2}\text{)}$. For convenience, K'_{spA} was expressed in terms of the apparent solubility product of calcite²⁰:

$$K'_{\text{spA}} = \rho K'_{\text{spC}} \quad (6)$$

Solubility analysis¹⁴ and partial molal volume data indicate that the effects of temperature and pressure on ρ are quite small compared with the changes in ρ attributable to variations in aragonite surface chemistry. K'_{spC} was calculated according to the methods of Millero¹¹ and Feely *et al.*¹⁰; values of ρ representative of the range of $K'_{\text{spA}}/K'_{\text{spC}}$ values obtained in detailed solubility analyses were used to calculate K'_{spA} . The values of ρ used here correspond to the lowest and highest values of ρ , 1.45¹⁸ and 2.05¹⁶ respectively, at 25°C and 35‰; and to the ratio,

Fig. 3 *a, b*, The predicted cumulative % dissolution of pteropod shells in the North Pacific versus depth for representative initial settling velocities. The initial settling rates appropriate to each species are based on results obtained in our laboratory. The scales adjacent to each pteropod species represent a length of 1 mm. *b*, A single pteropod species was observed in the highly undersaturated waters at the northernmost station.

$\rho = 1.78$, appropriate to the use of Berner's K'_{spA} data¹⁵ in the dissolution analyses of Morse *et al.*¹⁶ and Keir⁷.

Aragonite dissolution rates

Examination of the residual sum of squares surfaces (RSS, k , n , ρ) generated by our data and the dissolution model, equation (4), produced the following results. First, the data could not be satisfactorily modelled using values of ρ as small as 1.45. Second, the best description of our results is provided by the equation

$$R = 125 \left[1 - \frac{m_{\text{Ca}} m_{\text{CO}_2}}{2.05 K'_{\text{spC}}} \right]^{4.1} \quad (7)$$

Third, the best fit model obtained with $\rho = 1.78$ produced reasonable descriptions of the data, only slightly inferior to the best fit results from equation (7)

$$R = 130 \left[1 - \frac{m_{\text{Ca}} m_{\text{CO}_2}}{1.78 K'_{\text{spC}}} \right]^{3.1} \quad (8)$$

Our dissolution rate results can be compared with the dissolution models of Morse *et al.*⁶ and Keir⁷. The dissolution rate equation of Keir⁷ is given by

$$R(\% \text{ per day}) = 318(1 - \Omega)^{4.2} \quad (9)$$

Morse *et al.*⁶ described their dissolution rate results using two

Fig. 4 The typical surface transformations accompanying pteropod dissolution. **a**, A smooth surface (*C. columnella*, scale bar 500 μm) typical of all large, rapidly settling species found in our sediment traps. **b**, Pteropods not exposed to undersaturated seawater exhibit smooth surfaces, even under high magnification (scale bar 10 μm). **c**, In contrast, the very thin-walled, slowly settling species, *L. inflata* (scale bar 100 μm) exhibits considerable surface etching. **d**, Under high magnification (scale bar 10 μm) this individual, taken from 2,100 m at 35° N, 165° E, shows the sharply contrasting surface characteristics typical of partially dissolved, slowly settling species.

equations. For $\Omega_A \geq 0.44$ they obtained the result

$$R(\% \text{ per day}) = 110(1 - \Omega)^{2.93} \quad (10)$$

and for higher degrees of undersaturation ($\Omega_A \leq 0.44$) they obtained

$$R(\% \text{ per day}) = 1,318(1 - \Omega)^{7.27} \quad (11)$$

Despite apparent differences in equations (7)–(11), the dissolution rate predictions of each are generally in good agreement. The dissolution rate predictions obtained here and by Morse *et al.*⁶ and Keir⁷ are compared (Table 1). In examining their predictions for the conditions of our experiments, we assumed a value of $\rho = 1.78$. This is consistent with their use of Berner's K'_{SPA} values.

The dissolution rates shown in Table 1 indicate that the determinations of Morse *et al.* and Keir provide good first-order predictions for the dissolution of aragonite in the oceans. This is important because previous comparisons have been either semiquantitative^{6,21} or in very poor agreement^{8,9} with laboratory results. In agreement with Morse *et al.*⁶ and Morse and Berner¹³, our results indicate that the *in situ* devices of Milliman⁸ and Honjo and Erez⁹ produced saturation states significantly exceeding the surrounding seawater.

Differences in the results obtained here and by Morse *et al.* and Keir can be attributed to a variety of factors. The enhanced dissolution rates observed by Keir are probably the result of using pteropod fragments rather than whole pteropods. The inner surfaces of intact pteropods have a somewhat limited availability for dissolution. Consequently, the experiments of Keir were conducted using materials of a somewhat larger surface area to mass ratio than the intact pteropods used here. The results of Morse *et al.*⁶ are in remarkable agreement with our results, except at high degrees of undersaturation. This indicates that our results are commensurate with equation (10) but not equation (11). This may indicate that, in the low temperature environment of the deep ocean, the change in reaction order observed at $\Omega_A = 0.44$ by Morse *et al.*⁶ occurs at much higher degrees of undersaturation. Finally, in agreement with

the solubility analyses of Morse *et al.*¹⁸, our results indicate that whereas lower bound K'_{SPA} values are reasonably well defined, the upper bound K'_{SPA} values appropriate to freshly collected pelagic aragonitic particulates are not well defined. $K'_{\text{SPA}}/K'_{\text{SPC}}$ ratios appropriate to freshly collected aragonite in undersaturated seawater appear to exceed significantly the ratio attained after long equilibration periods.

Water column dissolution of pteropods

The results given in equations (7)–(11) can be used to examine the cumulative dissolution of pteropods settling through the oceanic water column. Using the carbonate system characterizations (Ω_C versus depth) at two of our stations in the North Pacific¹⁰ we have calculated the cumulative % dissolution of pteropods settling at a mid-range rate²² of 1.4 cm s⁻¹. The results of this analysis at two locations along the cruise track are shown in Fig. 2.

At a mid-range settling rate, pteropods in transit to the floor of the Pacific Ocean will undergo substantial dissolution (Fig. 2). At high latitudes, dissolution rates are appreciable at shallow depths, whereas at low latitudes dissolution becomes appreciable at depths below 1 km. It is important to recognize that Fig. 2 was constructed without considering the decrease in settling velocity which accompanies mass loss. Therefore, we regard the extents of dissolution shown in Fig. 2 as lower bound estimates for the initial, 1.4 cm s⁻¹ settling velocity.

Analysis of the influence of mass loss on settling velocity is complicated by considerable variations in pteropod morphology. Nevertheless, a reasonable first-order assessment of the effect of mass loss on settling velocity can be constructed by assuming the following relationship:

$$v \equiv v_0 \left(\frac{m}{m_0} \right) \quad (12)$$

where v is pteropod settling velocity, v_0 is initial pteropod settling velocity, m_0 is initial pteropod shell mass, and m is pteropod shell mass corresponding to velocity v . Equation (12) is appropriate where substantial mass losses occur without

Fig. 5 Advanced stages of dissolution in smaller size class pteropods (immature *L. inflata*) found in the 2,100-m sediment traps at 35° N, 165° E. *a*, In this individual (scale bar 100 μ m) only a very small portion of the original smooth surface remains. *b*, The considerable surface roughening which occurs after extended exposure to highly undersaturated seawater.

appreciable changes in particle volume and, as such, is applicable to thin-walled shells until onset of fragmentation. Figure 3 shows the predicted dissolution behaviour of pteropods at several initial settling velocities, using equation (12) to account for reductions in settling velocity.

Discussion

Although our inability to deal with the consequences of shell fragmentation makes the predictions shown in Fig. 3 somewhat uncertain, it is clear that the influence of mass loss on settling rate can produce striking differences in the behaviour of pteropod shells in the water column. Shells settling at a mid-range rate are substantially dissolved before reaching the ocean floor. Shells settling with an initial velocity of 100 cm s^{-1} , appropriate to a major size class (juvenile *Limacina inflata*) observed in our mass flux investigations dissolve in the upper water column of the Pacific Ocean. It is important to note, however, that even in the corrosive waters found in the Pacific, large pteropods such as *Cuvierina columnella* undergo relatively minor dissolution before reaching the ocean floor. This explains the otherwise disconcerting observations that pteropods are found on the uppermost sediment of box cores²³ and as empty shells in the deep water column of the Pacific Ocean²⁴.

The results shown in Figs 2 and 3 have important implications in the interpretation of CaCO_3 flux measurements in the ocean.

Long-duration sediment trap deployments in undersaturated seawater will lead to large underestimations of aragonite fluxes. The aragonite fluxes observed by Betzer *et al.*², using short-duration sediment trap deployments, are quite substantial compared with previous results obtained through long-term collections. The flux measurements of Betzer *et al.* are lower bound estimates: large mobile pteropods which may have been able to swim into our sediment traps were not included in their estimates; because some accounting of large pteropod contributions to mass flux is certainly necessary, the significance of aragonite in the Pacific Ocean could exceed considerably the lower bound estimates. As an example of the potential significance of large pteropod species, the ratio of large-pteropod mass flux at 400-m depths to the small-pteropod mass flux reported in the conservative account of Betzer *et al.* is about 5:1.

Analysis of our sediment trap collections in the northwest Pacific Ocean indicates that pteropod shells having diameters <500 μm constitute at least 50% of the aragonite fluxes reported by Betzer *et al.*² for 100-m water depths. Shells in this size class, or smaller, should undergo extensive dissolution in the upper water column. Scanning electron microscopy of individuals in various pteropod size fractions provides direct evidence of extensive surface etching in the smaller size classes at relatively shallow depths. Figure 4 shows the contrasting dissolution features of the large rapid-settling pteropod species *C. columnella* and the small fragile species *L. inflata*. The smooth surface of *C. columnella*, even under considerable magnification (Fig. 4b), is typical of all large pteropod species collected in the deepest, 2,100 m, sediment traps. In contrast (Fig. 4c,d), *L. inflata* and other small pteropod species collected at 2,100-m depths exhibit extensive surface etching. At 2,100-m depths, slow-settling species have been in contact with undersaturated Pacific waters long enough (~ 1 –2 days) to have lost a considerable portion of their original integument. The smallest size fraction in our collections gave evidence of advanced dissolution: the *L. inflata* shell (Fig. 5) has retained only a small fraction of its original smooth surface; Fig. 5a shows the aragonite surface which initially results from loss of this integument; Fig. 5b shows the considerable roughening of the aragonite surface on further dissolution. The shell transformations exhibited by the small specimen in this figure should be characteristic of a shell settling at about 1 cm s^{-1} at 35° N (Fig. 3a). The abundant small size class aragonitic particulates observed in our studies should provide substantial contributions to the alkalinity of the upper water column of the Pacific Ocean. As such, we think that pteropods should be identified as the principal source of 'excess alkalinity' in the Pacific Ocean, described by Fiadeiro³.

According to Berner Berner and Honjo²⁵ and Betzer *et al.*², aragonite appears to be a major component of the marine CO_2 system. The results presented here indicate that aragonitic particulates should undergo substantial transformations in the upper water column of the Pacific Ocean. The relatively rapid dissolution kinetics observed in this study and previously^{6,7} indicate that detailed experimental assessments of aragonite fluxes in the Pacific Ocean should be conducted in a manner minimizing sample transformations subsequent to collection. This work, in conjunction with the analysis of Betzer *et al.*, provides substantial evidence that the appearance of alkalinity anomalies, in waters substantially supersaturated with respect to calcite³ can be attributed to water column dissolution of aragonitic pteropods.

We thank Captain Raymond Speer and the crew of the RV *Discoverer* for their effective assistance during our analyses; chief scientist Joel Cline for administering diverse research activities at sea, Chief Bosun Warren Sherril for sediment trap deployments and retrievals; Dr. John A. McGowan for discussions on the characteristics of pteropods in the Pacific Ocean; Anthony Grew for scanning electron microscope analyses and Thomas Kuba for computer programming assistance. This research was supported by a grant (NA80RAD00020) from the National Oceanic and Atmospheric Administration Air

Resources Laboratory and is Contribution No. 740 from Pacific Marine Environmental Laboratory. We acknowledge a Graduate Council Fellowship award to J.G.A. from the University of South Florida.

Characterization of the human factor VIII gene

Jane Gitschier, William I. Wood, Therese M. Goralka, Karen L. Wion, Ellson Y. Chen, Dennis H. Eaton, Gordon A. Vehar*, Daniel J. Capon & Richard M. Lawn

Departments of Molecular Biology and * Protein Biochemistry, Genentech, Inc., 460 Point San Bruno Boulevard, South San Francisco, California 94080, USA

The complete 186,000 base-pair (bp) human factor VIII gene has been isolated and consists of 26 exons ranging in size from 69 to 3,106 bp and introns as large as 32.4 kilobases (kb). Nine kb of mRNA and protein-coding DNA has been sequenced and the mRNA termini have been mapped. The relationship between internal duplications in factor VIII and evolution of the gene is discussed.

HAEMOPHILIA has been known for millennia to be a male-specific, inherited disease¹. Haemophilia A afflicts 10-20 per 100,000 males; a relatively high proportion due to novel mutations of the factor VIII gene^{2,3}. The high frequency of haemophilia A compared with other autosomal clotting disorders results from the location of this gene on the X chromosome; one affected gene will thus produce the disease state in males. We report here the isolation and characterization of the 186,000 base pair (bp) region of the human X chromosome containing the complete factor VIII gene. A set of overlapping bacteriophage and cosmid clones was used to map and sequence the 26 exons containing the approximately 9,000 bp of coding sequence. Accompanying articles describe the expression of active human factor VIII from recombinant DNA clones⁴ and present the detailed characterization of the protein⁵. Our results provide a basis for studies of the molecular defects associated with haemophilia.

Factor VIII genomic clones

Initial factor VIII clones were recovered from a bacteriophage λ genomic library⁶ (λ 4X) containing DNA derived from an individual with 4X chromosomes (karyotyped 49,XXXXY). This library was screened with a unique 36-base oligonucleotide probe ('8.3'), synthesized to represent one codon choice of a sequenced tryptic peptide recovered from purified human factor VIII⁷. These initial clones contained overlapping segments spanning 28 kilobases (kb) of the human X chromosome. We subsequently expanded the set of genomic clones to contain 200 kb of the human genome encompassing the entire factor VIII gene. Both bacteriophage λ and cosmid clones were used in the process of 'genomic walking' (see legends to Figs. 1 and 2).

The restriction endonuclease map of the human factor VIII gene is shown in Fig. 1; the gene map was confirmed by the characterization of at least two independent clones for most of the 210-kb region and by numerous Southern blots of 49,XXXXY and normal DNA. No noticeable discrepancies between genomic DNA and the map derived from recombinant clones were found. In addition, low stringency blot experiments

have so far detected no closely related factor VIII genes or pseudogenes.

DNA sequence analysis

The DNA sequence of the entire mRNA coding portion (~9 kb) of the factor VIII gene has been determined. Exon-containing restriction fragments of genomic clones were identified by hybridization to cDNA and sequenced by dideoxy-chain termination procedures⁸. This DNA sequence analysis is distinct from that of cDNA clones derived from AL-7 cell RNA (see ref. 4). The genomic DNA sequence of exon boundaries (Fig. 3) and the promoter and polyadenylation regions (Fig. 4) are reported here. We found only two nucleotide differences between the genomic and cDNA sequences in the 8,860 nucleotides compared. Nucleotide 3,780 in cDNA is the G of a glutamic acid codon GAG, whereas in the cloned genomic DNA it is C, creating the conservative substitution of an aspartic acid residue. Nucleotide 8,728 in the 3' untranslated region is G in cDNA and A in genomic DNA. The surprising degree of similarity between genomic sequence derived from the 49,XXXXY cell DNA and cDNA sequence from AL-7 cell RNA indicates that the sequence data and the reverse transcription process are reliable and suggests also a lower level of nucleotide sequence polymorphism of this X-linked gene than has been found for some autosomal genes, an effect noted for other X chromosome loci⁹.

The boundaries of exons shown in Fig. 3 were established by restriction mapping and DNA sequence comparison of cDNA with genomic clones. In cases of nucleotide redundancy at either side of an intron, boundaries were chosen to be consistent with established consensus splice sites^{8,9}. All of the splice donor and acceptor sites conform to the GT...AG rule for nucleotides immediately flanking exon borders (Fig. 3). Further flanking sequences are in general agreement with favoured nucleotide frequencies noted in other compendia^{8,9}. The dinucleotide AG never occurs in the pyrimidine-rich region encompassing the final 15 nucleotides of introns; exons frequently begin with the sequence GT.

Fig. 1 Map of human factor VIII gene. The structure of the gene is schematically represented by an open bar; the 26 exons are filled-in areas drawn to scale. The direction of transcription is from left to right. The size scale in kb is drawn above the gene; the initiating ATG is positioned at nucleotide 1. Immediately below the gene are the extent of the triplicated 'A' domain, the unique 'B' domain, and the duplicated 'C' domain. The location of the recognition sites for the 10 restriction enzymes used to map the factor VIII gene are given in the next series of lines. Cross-hatched boxes represent the extent of human genomic DNA contained in each λ phage and cosmid clone. Other clones which encompass the same regions are not shown. No genomic clones span the 8.5 kb of intron located between clones λ 599 and p624. Other *EcoRI*, *BamHI* or *SstI* sites may lie in this region. The extent of this gap was determined by probing genomic Southern blots with single copy fragments isolated from the 3' end of λ 599 and the 5' end of p624. The bottom line shows the location of synthetic oligonucleotide or restriction fragment probes used in the genomic cloning, from left to right: the 2 probes used to map the uncloned region, three 5' walk probes, the original synthetic 36-mer probe '8.3'; three 3' walk probes.

Methods: λ and cosmid libraries were screened with random calf-thymus primed ^{32}P -labelled single copy genomic or cDNA probes²⁷. Nitrocellulose filters were hybridized overnight at 42 °C in 50% formamide, 0.1 g l⁻¹ salmon sperm DNA, 5 $\times$ SSC, 0.05 M sodium phosphate (pH 6.8), 5 $\times$ Denhardt's solution and 10% dextran sulphate²⁸. Filters were washed in 0.2 $\times$ SSC, 0.1 g l⁻¹ SDS at 60 °C for 1 h. Library filters were repeatedly rescreened with newly isolated walk probes so that extending clones were easily identified. To map restriction endonuclease cleavage sites, DNA from the clones was digested with restriction enzymes singly or in combinations and characterized by gel electrophoresis (followed by Southern blot hybridization in some cases). DNA fragments generated by *EcoRI* and *BamHI* digestion were subcloned into pUC plasmid vectors²⁹ for further propagation and analysis. Restriction mapping, DNA sequence analysis and blot hybridizations with the 8.3 probe determined the orientation of transcription of the gene. The genome walk was initiated by identifying single copy probe fragments near the ends of the initial 28 kb region. To find suitable fragments, digests of cloned DNA were blot hybridized with total ^{32}P -labelled human DNA under conditions where only DNA fragments containing sequences repeated more than about 50 times in the genome will hybridize^{30,31}. Candidate fragments were retested for repeated sequences by hybridization to 50,000 phage from the λ /4X library. To begin extension in the 5' direction, clone λ 222 was identified by a triplet of 1 kb *NdeI*/*BamHI* probe fragments isolated from λ 120 DNA. In the 3' direction, a single copy probe fragment of λ 114 failed to yield extending clones in screens of several λ libraries. Based on genomic blotting results, we then constructed a size selected³² *BclI* library of human 49,XXXXY DNA in the vector λ 1059³³. λ 482 is one of the extending clones so derived. Subsequent overlapping clones (p541, p542, p543, p612, p613 and p624) were derived by screening a recombinant cosmid library containing human DNA (see Fig. 2). The most 5' genomic clones, λ 599 and λ 605 were obtained by screening with cDNA-derived probes.

Fig. 2 Cosmid vector pGcos4. To facilitate genomic walking, we developed a new cosmid vector with the following features: (1) It can accommodate 45 kb inserts. (2) It confers resistance to tetracycline, rather than ampicillin. (3) The 641 bp *AvaI*/*PvuII* fragment of pBR322 has been removed to increase plasmid copy number and to delete sequences interfering with transformation of eukaryotic cells³⁴. (4) A methotrexate-resistant dihydrofolate reductase gene driven by a simian virus 40 (SV40) early promoter has been incorporated for the selection and propagation of clones in eukaryotic cells³⁵. (5) A synthetic DNA fragment containing a unique *BamHI* site flanked by pairs of *PvuI* and *EcoRI* sites has been inserted as the cloning site. The flanking *EcoRI* sites are useful for subcloning fragments and the *PvuI* sites allow excision of the entire insert in most cases, since this enzyme cuts eukaryotic DNA only about once per 135,000 bp. Construction: The scale is represented by dots within the circle numbered in kb from the zero point. The 403 base (b) annealed *HincII* fragment of λ c1857S7 (Bethesda Research Lab) containing the *cos* site was cloned in pBR322 from *AvaI* to *PvuII* to generate the plasmid pGcos1. Separately, the 1,624 b *PvuII* to *NaeI* fragment of pFR400³⁵ containing an SV40 origin and promoter, a methotrexate-resistant dihydrofolate reductase gene, and hepatitis B surface antigen polyadenylation sequences, was cloned into the pBR322 *AhaIII* site to generate the plasmid mp33dhfr. The following three fragments were ligated together to generate the cosmid vector pGcos3: 1,497 base (b) *SphI*-*NdeI* fragment of pGcos1, 2,163 b *NdeI*-*EcoRV* fragment of mp33dhfr and 376 b *EcoRV*-*SphI* fragment of pKT19. pKT19 is a derivative of pBR322 in which the *BamHI* site in the tetracycline resistance gene has been removed (provided by Herb Boyer). pGcos4 was generated by cloning the synthetic 20mer, 5' AATTCGATCGGATCCGATCG, in the *EcoRI* of pGcos3. Left and right arms of this vector were prepared by cleavage of two aliquots with *SstI* or *SalI*, followed by treatment with alkaline phosphatase, cleavage with *BamHI* and isolation of the large fragments²⁸. 49,XXXXY DNA isolated from the GM1202A cell line (NIGMS Human Genetic Mutant Cell Repository, Camden, New Jersey) was partially cleaved with five levels of *Sau3A1* and the 45 kb fragments isolated by sucrose density centrifugation²⁸. These fragments were ligated to the *BamHI* arms of pGcos4, packaged *in vitro* and used to infect *E. coli* HB101.

Fig. 5 Determination of the 5' mRNA start site by RNase protection. Autoradiograph of a 6% polyacrylamide, 7 M urea gel. Lanes 1 and 2, a known DNA sequencing ladder employed as size standards; lanes 3–11, results of RNase protection reactions.

Methods: Cell and tissue RNA was prepared³⁶. The 5' genomic *Sst*I fragment was ligated into pSP64 (a gift of P. Mellon and T. Maniatis) and linearized with *Pvu*II. The uniformly labelled ³²P-RNA probe was synthesized with 400 Ci mmole⁻¹ α -[³²P]CTP (Amersham) and SP6 RNA polymerase (NEN) followed by DNase treatment (DPRF, Worthington) as described^{12,13}. Sample RNAs were hybridized with 5 $\times$ 10⁵ c.p.m. of probe at 37°C and digested with 80 μ g ml⁻¹ RNase A and 4 μ g ml⁻¹ RNase T1 (Worthington) followed by extraction, electrophoresis and autoradiography. ³²P-labelled, anti-sense strand RNA probe was prepared by ligating the 1.2 kb *Sst*I genomic fragment containing exon 1 and 5' flanking sequences into pSP64¹² and transcribing the linearized plasmid with SP6 RNA polymerase^{12,13}. This labelled probe was hybridized with poly(A)⁺ RNA derived from various sources and digested with RNase A and RNase T1 before electrophoresis. Protected RNA was derived from: lane 3, AL-7 human hybridoma cells (10 μ g); 4, human liver sample 1 (10 μ g); 5, human liver sample 2 (10 μ g); 6, human Alexander cell line (10 μ g); 7, human Hep G2 cell line (10 μ g); 8, peripheral blood lymphocyte sample 1 (3 μ g); 9, peripheral blood lymphocyte sample 2 (3 μ g); 10, mouse T lymphoma cell line S49 (10 μ g); 11, no RNA control. An identical pair of protected fragments (arrow), measuring 185 and 187 bases from the *Sst*I site, appear only in RNA obtained from the two human liver samples and the AL-7 hybridoma cells. This positions the probable 5' mRNA start site at ~170 bases 5' of the initiation ATG as shown in Fig. 4. (As RNases A and T1 cannot cleave after an adenosine residue and the complementary strand is radiolabelled, no protected band was seen corresponding to a terminus at position -171 of the gene (Fig. 4), which is a T residue in the genomic sequence.)

the protected RNA is bounded by an intron instead of the true mRNA 5' start site.

The RNase protection experiments also show that liver is a site of synthesis of factor VIII. No factor VIII RNA was detected in the other tissues of the protection experiment shown in Fig. 5 nor by Northern blot analysis of RNA from various tissues and cell lines⁴. Liver is only one of several candidates for the site of factor VIII production^{14–16}.

Inspection of the genomic sequence of the 5' flanking region (Fig. 4a) revealed the sequence GATAAA beginning 30 bp 5' of the presumed 5' mRNA start site, similar to the canonical 'ATA' or 'Goldberg-Hogness' sequence, located about 25–35 bp before eukaryotic cap sites and apparently required for precise initiation of transcription by RNA polymerase II^{17,18}. We found no convincing candidate for the less frequently conserved 'CAT' sequence¹⁹ in the -70 bp region.

One additional ATG to nucleotide 5' to +1 is found in the 5' untranslated region at position -131 (Fig. 5). This region cannot serve as the translation start site for factor VIII because seven stop codons, distributed in all three possible reading frames, occur in the 128 nucleotides between this upstream ATG and position +1. Although only 5% of the previously compiled eukaryotic mRNAs contain an ATG 5' of the translation initiation site²⁰, the presence of an upstream ATG does not necessarily repress translational initiation at the proper start site when it is followed by an in-frame termination codon²¹.

The 3' untranslated region of the factor VIII gene contains 1,805 nucleotides (counting the TGA stop triplet and terminating before the first A of the poly(A) tail; Fig. 4b). The site of polyadenylation was inferred from cDNA clones and is preceded 19 bases by the common polyadenylation signal AATAAA²² as well as a second, less conserved recognition element CATTG²³.

Fig. 6 Homologous factor VIII domains and intron boundaries. **a**, 'A' unit triplication showing the alignment of three amino acid sequences. The amino acid numbers precede each line. Arrows indicate the location of introns and are flanked by the appropriate exon numbers. *, Conserved amino acids. **b**, 'C' unit duplication. **c**, Representation of the A and C repeat units with the location of introns indicated by vertical lines. The exons are numbered.

Introns and protein domains

Searches for internal homologies in the factor VIII DNA sequence and the derived amino acid sequence revealed three types of domains: a triplicated 'A' unit of 330–380 amino acids, a unique 'B' unit of about 925 amino acids and a duplicated 'C' unit of about 160 amino acids. The order of the domains in the gene and protein is A1–A2–B–A3–C1–C2 (refs 4, 5; Fig. 1) (note that the exons constituting each domain are not clustered). The amino acid alignment of the A and C repeats (Fig. 6) demonstrates that the A units have ~30% pairwise amino acid homology (20% of the residues being conserved in all three domains), whereas the two C units have 37% homology^{4,5}.

If segmental DNA duplication has played a role in the evolution of the large factor VIII gene, one might expect a conservation of the intron boundaries within the A and C repeats of factor VIII. The alignment of most intron boundaries relative to the protein coding sequence is well fixed by the high degree of homology in the A and C repeats (Fig. 6). For the C duplication, intron boundaries occur precisely at the borders of the C1 and C2 repeats, as would be expected for a DNA duplication mechanism where the boundaries fall within the introns. Furthermore, the junction between A3 and C1 also contains an intron precisely at the boundary, again as expected for an intron joining mechanism. On the other hand, the A1–A2 and A2–A3 junctions are each contained on one exon (Fig. 6).

Within the A and C repeats only some of the intron boundaries

are conserved. In fact, each of the repeats contains a different number of exons. The precise alignment of some intron boundaries within the A and C repeats suggests that these introns were present in an ancestral precursor of the repeat units and duplicated in the course of the event that generated the repeat. The non-aligned introns appear to have arisen since the duplication, either by loss of one member of a duplicated intron or by the insertion of new introns after the duplication. In an analogous situation, α -feto protein and albumin each have a triplicated gene structure, but unlike factor VIII, all of the nine intron boundaries within the repeats for these two genes are conserved precisely²⁴⁻²⁵.

It is also interesting to speculate as to the origin of domain B in factor VIII. The 925 amino acids of this domain encompass nearly all of the 3.1 kb of exon 14, where the end of the A2 repeat (at the 5' end) and the start of the A3 repeat (at the 3' end) are also found. This suggests that during the course of evolution a processed gene may have been inserted into a short exon that contained the A2-A3 boundary. Insertion of a processed gene (derived from an mRNA) would also account for the anomalously large size of exon 14. The B domain connects the *M*_r 90,000 (made up of A1 and A2) and the *M*_r 80,000 (A3, C1, C2) fragments of the factor VIII protein. Proteolytic removal of the domain is associated with activation of the protein^{5,11}.

thus exon 14 is related to a physiological unit of the protein. Whether any other functional domains or subdomains of factor VIII correspond to any of the exons awaits further characterization of the molecule.

In conclusion, we report here the complete isolation and characterization of the human factor VIII gene. It is the largest gene yet characterized, encompassing nearly 0.1% (186 kb) of the human X chromosome. Transcription of such a large gene could take over three hours (based on a transcription rate of 15 nucleotides per second²⁶). Probes derived from the factor VIII gene will allow identification of restriction fragment length polymorphisms which can be used further to localize the gene on the X chromosome and lead to improved prenatal diagnosis of haemophilia. We anticipate that the knowledge of the gene structure and DNA sequence will be invaluable in the analysis of the molecular basis of haemophilia.

We thank John McGrath who characterized the λ 222 clone and Philip Hollingshead for laboratory assistance; Edward Tuddenham, David Martin, Ingrid Caras and Glenn Nedwin for providing tissue samples; Jeanne Arch and Alane Gray for preparation of the manuscript and figures. We thank David Goeddel, Christian Simonsen, Laurence Lasky and Dennis Kleid for helpful discussions and David Martin and Robert Swanson for their support.

DNA clones encoding the complete 2,351 amino acid sequence for human factor VIII have been isolated and used to produce biologically active factor VIII in cultured mammalian cells. The recombinant protein corrects the clotting time of plasma from haemophiliacs and has many of the biochemical and immunological characteristics of serum-derived factor VIII.

A CRITICAL factor in the arrest of bleeding is the activation of the coagulation cascade, a system consisting of over a dozen interacting proteins present in plasma or released from cells^{1,2}. A small stimulus at the beginning of the cascade is catalytically amplified at each step such that the final outcome is the rapid conversion of the soluble protein fibrinogen into its insoluble

form, fibrin, which stabilizes the platelet plug. The lack or deficiency of any of the proteins involved in the coagulation cascade blocks the propagation of the initial stimulus. In the middle of the cascade is a step wherein factor IXa, in conjunction with factor VIII, converts factor X to the activated form, factor Xa. Factor VIII acts as a cofactor at this step, being required

Fig. 1 Detection of the factor VIII gene with probe 8.3, 5'-CTTTTCAGGTCAACGTCGGAGAAATAAGCCCAAGC, a 36-base long probe synthesized based on the sequence of a 12 amino acid tryptic fragment of factor VIII, AWAYFSDVDLEK (ref. 5). **a**, Southern blots of 46,XY (1X, male) DNA and 49,XXXXY (4X) human DNA (isolated from cell line GM1202A, NIGMS Human Genetic Mutant Cell Repository, Camden, New Jersey) digested with *EcoRI* and *BamHI* were hybridized with ^{32} P end-labelled 8.3 probe in $6\times$ SSC, 50 mM sodium phosphate (pH 6.8), $5\times$ Denhardt's solution, 0.1 g l^{-1} boiled, sonicated salmon sperm DNA, 20% formamide and 10% dextran sulphate at 42°C . The three blots were washed in $1\times$ SSC, 0.1% SDS at the temperature indicated. Lane 1, *EcoRI* 1X; lane 2, *EcoRI* 4X; lane 3, *BamHI* 1X; lane 4, *BamHI* 4X; lane M, end-labelled λ HindIII and Φ X174 *HaeIII* digested marker fragments. **b**, One nitrocellulose filter from the screen of cloned 4X human DNA hybridized with probe 8.3. This library was constructed by partially digesting 4X DNA with *Sau3AI* and ligating the 15 kb size fraction into the vector λ Charon 30 (ref. 42). Arrows, the independent factor VIII positive clones. Hybridization and washing for the library screen was as described above for the Southern blots with a wash temperature of 37°C .

with calcium ions and phospholipid for the activity of factor IXa. The two most common haemophilic disorders are caused by the decreased function of either factor VIII (haemophilia A or classic haemophilia; 80% of all cases) or factor IXa (haemophilia B or Christmas disease). The clinical manifestation in both types of disorders is the same: a lack of sufficient fibrin formation resulting in prolonged bleeding.

Several decades ago the mean age of death of haemophiliacs was less than 20 years; between 1950 and 1970, however, research into the factor VIII disorder led to the treatment of haemophilia A, first with whole plasma and, later, with plasma concentrates. Human plasma is both an inefficient and expensive source of this labile protein which is present at only $100\text{--}200\text{ ng ml}^{-1}$ (ref. 3). Pharmaceutical products currently available are highly impure ($<1\%$ factor VIII) and some are produced

Table 1 Assays of recombinant factor VIII activity

Sample	Coatest assay (units ml^{-1})	Radioimmune assay (units ml^{-1})	
		C7F7 Ab	C10 Ab
62.2 supernatant	0.07	0.28	0.34
62.2 supernatant + C7F7	<0.01	—	—
62.2 supernatant + Synbiotic	<0.01	—	—
Control supernatant	<0.01	<0.001	<0.001
62.2 cell lysate	—	0.1	0.1

Culture supernatant from recombinant factor VIII producing 62.2 cells, with and without inhibiting monoclonal antibodies, was subjected to the chromogenic 'Coatest' or to radioimmune assays. The Coatest assay (Helena Labs) was performed by diluting $5\text{ }\mu\text{l}$ of 62.2 supernatant with $45\text{ }\mu\text{l}$ 0.05 M Tris, pH 7.3 containing 0.2% bovine serum albumin (BSA) and incubating this mixture with or without either $5\text{ }\mu\text{g}$ C7F7 or Synbiotic factor VIII monoclonal antibodies. Both these antibodies react with the M_r 80,000 subunit of plasma-derived factor VIII. After 5 min at 24°C , $50\text{ }\mu\text{l}$ of a mixture containing factor IXa, factor X and phospholipid was added and samples incubated for 5 minutes at 37°C . $50\text{ }\mu\text{l}$ of each of 25 mM CaCl_2 and S-2222 chromogenic substrate was added and after 10 min at 37°C the reaction stopped by the addition of 50% acetic acid. The assay was repeated with control cultures and calibrated with normal human plasma. One factor VIII unit is equivalent to the amount of factor VIII in 1 ml normal human plasma. Radioimmune assays: The 96 wells of a microtitre dish were coated overnight with $100\text{ }\mu\text{l}$ 50 mM NaHCO_3 buffer, pH 9.6, containing 2.5 mg l^{-1} of C.C. antibody purified by protein A-Sepharose chromatography. The wells were washed three times with $200\text{ }\mu\text{l}$ of phosphate-buffered saline (PBS) containing 0.05% Tween 20, blocked with $200\text{ }\mu\text{l}$ of PBS containing 0.1% gelatin and 0.01% merthiolate for 1–2 h, rewashed as before and $100\text{ }\mu\text{l}$ of sample added and incubated overnight. The wells were washed and $100\text{ }\mu\text{l}$ of ^{125}I labelled C10 or C7F7 antibody ($1,000\text{ c.p.m. }\mu\text{l}^{-1}$) added and incubated for 6–8 h. The wells were washed again and counted. Standard curves were derived from samples of normal plasma. Antibodies used in assays and columns were: C.C., a polyclonal antibody derived from the plasma of a severely affected haemophiliac⁴⁰; C8 and C10, neutralizing monoclonals binding to the M_r 210,000 and 90,000 fragments of factor VIII, supplied by A. H. Goodall, Department of Immunology, Royal Free Hospital, London⁴¹; C7F7, a neutralizing monoclonal binding to the M_r 80,000 fragment of factor VIII, derived at Genentech by Badora Streck and an 80,000 binding monoclonal obtained from Synbiotic Corporation.

from pooled plasma lots derived from thousands of donors. Thus, these products are associated with a variety of serious complications caused by protein precipitates as well as the possible contamination by adventitious agents such as hepatitis virus and the agent responsible for acquired immune deficiency syndrome (AIDS).

Factor VIII is a molecule of relative mass (M_r) 300,000 (ref. 4). In attempts to produce pure homogenous factor VIII, we have identified clones containing the factor VIII gene using oligonucleotide probes based on the protein sequence data reported in an accompanying paper⁵. We also show that cloned full-length factor VIII protein coding sequences assembled into a plasmid direct the synthesis of biologically active factor VIII when transfected into cultured mammalian cells.

Isolation of genomic clones

Two factors contributed to our decision to initially screen recombinant genomic libraries (rather than RNA-derived cDNA libraries) for the factor VIII gene. First, the site of synthesis of factor VIII is uncertain, although the liver is considered the most likely source^{6–10}. Second, the concentration of factor VIII in plasma is extremely low (200 ng ml^{-1}), about $1/2,000,000$ the molar concentration of serum albumin. Thus, it was not clear that cDNA libraries made from mRNA of a given tissue would yield any factor VIII clones.

Therefore we adopted a strategy of first identifying a genomic clone corresponding to a sequenced portion of the factor VIII protein. Then several paths could be followed. An exon-containing restriction fragment could be used to identify a

Fig. 2 cDNA cloning procedure. **a**, 25 μ g poly(A)⁺ RNA from the AL-7 cell line was electrophoresed in a 1% agarose gel containing 6% formaldehyde⁴², transferred to nitrocellulose and hybridized in 5 $\times$ SSC, 5 $\times$ Denhardt's solution, 10% dextran sulphate, 50% formamide, 0.1% SDS, 0.1% sodium pyrophosphate, 0.1 mg ml⁻¹ *E. coli* tRNA at 42°C overnight with ³²P-labelled probe prepared from the 189 bp *Stu*I/*Hinc*II genomic clone fragment containing exon 16 sequence. Wash conditions were 0.2 $\times$ SSC, 0.1% SDS at 42°C. This RNA was 0.0001–0.001% of the total cytoplasmic poly(A)⁺ RNA in the AL-7 cell line by comparison with control DNA dot-blot hybridizations⁴³. **b**, Factor VIII mRNA; open bar, mature protein coding region; hatched area, signal peptide coding region; adjacent lines, untranslated regions of the message. Left, the 5' end of the mRNA. Below the mRNA line are the six cDNA clones and the genomic clone containing exon 14 from which the full length factor VIII clone was assembled. cDNA synthesis primers 1–4 and oligo(dT) are shown with arrows depicting the direction of synthesis for which they are primed. Primer 1, 5' CAGGTCAA-CATCAGAG; primer 2, 5' TATCTGTGTGAGGGTG; primer 3, 5' AACTCTGTGTGTCAG; primer 4, 5' TATTGCTGCAGTGGAG. Probe A, 189 bp *Stu*I/*Hinc*II fragment from exon 16; probe B, 361 bp *Sau*3A1/*Stu*I fragment of p1.11; probe C, 324 bp *Hinc*II fragment from exon 14; probe D, 419 bp *Pst*I/*Hinc*II from p1.11. The original 36-mer probe 8.3 is located near the primer 1 region. Restriction endonuclease sites in the corresponding DNA are indicated by: B, *Bam*HI; E, *Eco*RI; H, *Hpa*I; K, *Kpn*I; S, *Sac*I; Sc, *Sal*I; X, *Xba*I.

Methods: the first cDNA clones were isolated by priming cDNA synthesis with primer 1 from exon 16. From 5 μ g AL-7 poly(A)⁺ RNA, approximately 100,000 *E. coli* transformants were obtained by introducing the double-stranded cDNA into pBR322 by the oligo(dC:dG) tailing method⁴². These clones were screened by hybridization to probe A⁴⁴ and a single clone containing a 447 bp cDNA insert (p1.11) (including the 5' 104 bp of exon 16) was isolated. The remaining sequences of p1.11 extended 5', including exon 15 and part of exon 14. Exon 14 had been found earlier by hybridization with an oligonucleotide probe based on protein sequence data¹⁶. Hybrid selection was used to further enrich for factor VIII specific sequences in AL-7 mRNA. To avoid degradation of the relatively large factor VIII transcripts, single-stranded cDNA was initially synthesized on a preparative scale and subjected to hybrid selection prior to conversion to double-stranded molecules. First-strand synthesis was performed on 200 μ g AL-7 poly(A)⁺ RNA with primer 1 and the resulting product was hybridized with an exon 16 DNA fragment (probe A), denatured and immobilized on DBM-cellulose paper⁴². After elution, 0.5–1.0 ng of single-stranded material was recovered and used to prepare 12,000 *E. coli* transformants. 29 clones were obtained by hybridization to probe B which did not overlap the DNA fragment used for hybrid selection. This represents a 240-fold enrichment of desired clones compared with the first cDNA library. DNA sequence shows that the two longest clones (p3.12, p3.48) extended about 1,500 bp further 5' than p1.11. Primer 3, located near the 5' end of exon 14, was used to isolate the N-terminal coding sequences for factor VIII. Double stranded cDNA was prepared and ligated to synthetic complementary *Eco*RI adaptors, 5'pCCTTGACCGTAAGACATG and 5'AATTCATGTCTTACGGTCAAGG. Upon annealing, these adaptors have a phosphorylated blunt end which will be covalently joined to the cDNA, as well as a cohesive *Eco*RI terminus with a 5'-hydroxyl group which cannot self-ligate, thus avoiding the need for methylation of the cDNA and subsequent *Eco*RI digestion. Approximately 1.5 $\times$ 10⁶ recombinant phage were obtained from 1 μ g AL-7 poly(A)⁺ RNA with primer 3 following removal of excess adaptor, insertion into λ gt10 and *in vitro* packaging^{42,45}. Forty-six clones were identified by hybridization with probe C. Several of the clones contained cDNA inserts which extended about 2,700 bp 5' of primer 3 and the DNA sequence of the two longest clones (λ 13.2 and λ 13.27) revealed the 5' terminus of the protein coding region (Fig. 3). (Primer 2 was only used subsequent to the cloning and expression described here to obtain cDNA sequence data corresponding to the region of genomic clone λ 222 containing exon 14.) To isolate the coding region for the C-terminus of factor VIII, a cDNA library was prepared from oligo(dT) primed AL-7 RNA. A 16-mer corresponding to the mRNA sequence found 400 bp upstream of the 3' end of exon 16 (primer 4) was included in the second strand reaction to increase its specificity. Four of a total 3 $\times$ 10⁶ λ gt10 clones hybridized with a fragment from p3.12 (probe D) located 3' of primer 4. DNA sequence analysis of the longest clone, λ 10.44, indicated that the cDNA insert began at primer 4 and extended for nearly 1,800 bp 3', but had not reached the end of the coding region. To identify clones containing the 3' end of the mRNA, the oligo(dT)-primed library was rehybridized with a probe prepared from the insert of λ 10.44. Twenty-four additional clones were recovered and the two longest of these (λ 10.3 and λ 10.9) were sequenced. Both clones overlapped λ 10.44 as expected and extended an additional 1,900 bp to the poly(A) tail.

suitable tissue or cell source of factor VIII by RNA blot hybridization. The mRNA from this source would be used to generate cDNA clones which could be screened by cloned genomic fragments. Concurrently, overlapping genomic clones could be isolated encompassing the entire factor VIII gene. Even if a direct mRNA source were not identified, exons from the genomic clones could be found and spliced together by simian virus 40 (SV40) recombinant 'exon expression' plasmids. In fact, we used information derived from all three paths.

A genomic library enriched for the X chromosome was constructed from DNA isolated from a lymphoblast cell line derived from an individual with four X chromosomes (karyotyped 49,XXXXY). To identify factor VIII clones, a series of oligonucleotide probes based on portions of the human factor VIII protein sequence⁵ was prepared by chemical synthesis. The oligonucleotide probes were of two types: unique long probes of 30–100 nucleotides based on codon usage analysis and mixtures of short probes of 14–20 bases specifying all possible combinations for each codon choice^{11–13}. The utility of probe 8.3 (Fig. 1 legend) was first tested by genomic blot hybridizations with normal male (1X) and 49,XXXXY (4X) DNA. Even at the highest stringency (1 $\times$ SSC, 46°C), a single *Eco*RI or *Bam*HI band was observed which had an intensity ratio of about 1:4 in the 1X and 4X lanes, as expected for the X-linked factor VIII gene (Fig. 1).

Next, 500,000 phage of the 4X genomic library were screened with probe 8.3 and 15 clones representing eight distinct overlapping recombinants were isolated and characterized (Fig. 1). The DNA sequence of the region hybridizing with the 8.3 probe included two continuous matches of 14 and 10 base pairs (bp) and had an overall homology of 83%. The first 10 of the 12 amino acid residues of the peptide fragment agreed with those deduced from the DNA sequence of the recombinant clones. The DNA sequence also predicted a lysine residue preceding

the peptide, as would be expected for the product of a tryptic digest. The final two residues did not match the DNA-predicted sequence; the DNA at this junction, however, contained a probable RNA splice donor sequence^{14,15} followed shortly by stop codons in all three possible reading frames.

Inspection of the open reading frame immediately 5' of the probe homology revealed matches with the protein sequence of several additional tryptic peptides from the *M_r* 80,000 factor VIII fragment⁷. The identity between highly purified factor VIII

Fig. 3 Sequence of human factor VIII gene, with nucleotides numbered at the left of each line. One, the A of the translation initiation codon ATG. Negative numbers, 5' untranslated sequence. (mRNA mapping experiments suggest that factor VIII mRNA extends ~60 nucleotides further 5' than position -109 shown here¹⁶.) The predicted protein sequence is shown above the DNA. Numbers above the amino acids are S1–19 for the predicted signal peptide, and 1–2,332 for the predicted mature protein. 'Op', the opal translation stop codon TGA. The 3' polyadenylation signal AATAAA¹⁸ is underlined and eight residues of the poly(A) tail (found in clone λ c10.3) are shown. The sequence homologous to the synthetic oligonucleotide probe 8.3 is also underlined (nucleotides 5,557–5,592). Selected restriction endonuclease cleavage sites are shown above the appropriate sequence. The entire factor VIII sequence was verified after assembly of cDNA and genomic clones in an expression plasmid. The complete DNA sequence of the protein coding region of the human factor VIII gene was also determined from the genomic clones we have described¹⁶. cDNA clones have been isolated covering all of the sequence shown except for nucleotides 3,042–3,216. The cDNA and genomic clones differ at only two positions: nucleotide 3,780 (underlined) is C in the genomic clone and G in cDNA (changing amino acid 1,241 from Glu to Asp), and nucleotide 8,728 (underlined) in the 3' untranslated region is A in the genomic clone and G in cDNA. DNA sequence analysis was performed by the dideoxy chain termination method using restriction fragments subcloned into single-stranded M13 vectors^{46,47}.

Fig. 5 Immunoaffinity chromatography of recombinant factor VIII. *a*, Chromatography on C7F7-Sepharose; *b*, chromatography on von Willebrand factor-Sepharose.

Methods: Serum free culture media of transformed cell line 62.2 containing 400 units of factor VIII was first adsorbed onto DEAE-sepharose (Pharmacia). The gel was washed subsequently with 0.05 M imidazole pH 6.9 containing 0.15 M NaCl, 0.01 M CaCl₂ and 0.02 M glycine ethyl ester; factor VIII was eluted with the same buffer containing 0.1 M CaCl₂. Material obtained from DEAE-sepharose was then passed through a factor VIII monoclonal antibody column. The column was prepared by covalently linking 2 mg factor VIII monoclonal antibody C7F7 to 1 ml of Affi-gel 10 (Bio-Rad). After loading, the column was washed sequentially with 20 volumes of 0.02 M imidazole pH 6.4 containing 0.15 M NaCl and 0.01 M CaCl₂ and 10 volumes of the same buffer containing 0.5 M NaCl. Factor VIII activity was eluted with 0.02 M imidazole pH 6.4 containing 1 M KI and 20% ethylene glycol and measured by the Coatest assay (Table 1). This figure depicts chromatography performed with the monoclonal antibody C7F7, known to react with the M_r 80,000 plasma-derived factor VIII protein fragment. Comparable results were obtained with a column using the C8 monoclonal antibody which binds to the M_r 210,000 and 90,000 fragments of factor VIII. The table inset of *a* shows the neutralization of coagulant activity by factor VIII antibodies. Partially purified recombinant factor VIII was dialysed into 0.05 M Tris pH 7.4 containing 0.15 M NaCl, then diluted with the same buffer containing 0.2% BSA. 50 µl aliquots of this sample were preincubated alone, with human factor VIII monoclonal antibodies (5 µg of either C7F7 or a human factor VIII monoclonal purchased from Synbiotics, Inc.), or with 5 µl of serum derived from a patient with a high factor VIII antibody titre⁴⁰ (C.C.) for 5 min at 24 °C. Factor VIII activity was then determined by coagulation assay. Briefly, 50 µl platelin (General Diagnostics) was incubated with 50 µl factor VIII deficient plasma for 8 min at 37 °C. 50 µl sample was then added and after 30 s at 37 °C, 50 µl 25 mM CaCl₂ was added and the clotting time measured. Supernatant from 62.2 cell cultures containing ~2 units of factor VIII activity was passed through a von Willebrand factor-sepharose column at 30 ml h⁻¹. The von Willebrand factor used here was purified as described previously⁵¹. von Willebrand factor-sepharose was prepared by covalently linking the protein to Affi-gel 10 (1 mg ml⁻¹ gel). After loading the column, it was washed with 5 volumes 0.05 M imidazole pH 6.9 containing 0.15 M NaCl, 0.01 M CaCl₂ and 0.02 M glycine ethyl ester. Factor VIII activity was eluted with the same buffer containing 0.25 M CaCl₂ and fractions assayed with the Coatest assay.

Fig. 6 Effect of thrombin and protein C on factor VIII activity.

a, Recombinant factor VIII obtained from immunoaffinity chromatography was dialysed into 0.05 M Tris pH 7.4 buffer containing 0.15 M NaCl and diluted to a concentration of 0.1 units ml⁻¹ with the same buffer containing 0.2% BSA (TBS buffer). Aliquots of this sample were then incubated either with thrombin at 0.01 units ml⁻¹ (closed circles) or without thrombin (open circles) for the times shown at 37 °C. At the given time points, factor VIII activity was determined by the coagulation assay described in Fig. 5 legend. Thrombin at the concentration used here did not decrease background clotting times of samples in which factor VIII was omitted. *b*, Recombinant factor VIII was diluted into TBS buffer to a concentration of 0.2 units ml⁻¹. 5 µl rabbit brain cephalin (Sigma) and CaCl₂ to 5 mM were added to 50 µl aliquots of this sample. Subsequently these samples were incubated with activated protein C (provided by Walter Kiesel, University of Washington) at 0.4 mg ml⁻¹ (closed circles) or with no addition (open circles) for the times shown at 37 °C. Residual activity was then determined as described above.

dihydrofolate reductase cDNA transcribed by an SV40 early promoter to provide a selectable marker when expressed in mammalian cells²⁵. The plasmid was introduced into a hamster kidney cell line by the calcium-phosphate coprecipitation method^{25,26}; we chose one clone, 62.2, for further study.

To characterize the expression of factor VIII in the 62.2 cell line, RNA was extracted from cells and analysed by Northern blot hybridization. A predominant 9 kb RNA from 62.2 cells, but not from untransfected control cells, was found to hybridize both with a probe specific for factor VIII and with one containing hepatitis B surface antigen 3' sequences (data not shown). The intensity of the hybridizing signal with 62.2 RNA was 200 times greater than that observed with RNA prepared from the AL-7 cell line. Radioimmune assays for factor VIII were also performed on the 62.2 supernatant and cell lysate (Table 1). Monoclonal antibodies directed against the N-terminal M_r 210,000 fragment (C10) or the C-terminal M_r 80,000 fragment (C7F7) of serum-derived factor VIII detected a 300-fold increase in factor VIII cross-reacting activity in 62.2 cells over that found in control cells (Table 1).

Biochemical properties

The activation of natural factor X by factor IXa is dependent on factor VIII, which is the basis of the 'Coatest' assay we have used to estimate factor VIII in cell supernatants; we find significant activity in 62.2 supernatants but not in those from control cells not transfected (Table 1). Supernatant from 62.2 cells alone did not catalyse the cleavage of the chromogenic substrate. In addition, incubation of 62.2 cell supernatants with either of two monoclonal antibodies directed against the M_r 80,000 fragment of factor VIII (C7F7 and Synbiotic) completely neutralized the observed activity (Table 1).

To characterize further the factor VIII secreted by 62.2 cells, partially purified protein was tested for the ability to reduce the clotting time of plasma from patients with haemophilia A. Protein from 62.2 cell supernatants was affinity purified on a monoclonal antibody column under the same conditions used factor VIII isolated from human plasma (Fig. 5a). Diluted protein samples from the immunoaffinity column reduced the clotting time of plasma from a haemophilia A patient from 120 s to 65 s (equivalent to the clotting time for a 1:10 dilution of normal plasma). This activity was neutralized by the C7F7 and Synbiotic monoclonal antibodies directed against the M_r 80,000 fragment of factor VIII as well as by the patient-derived polyclonal antibody, C.C. (Fig. 5a).

Factor VIII circulates in plasma as a complex with the von Willebrand protein^{27,28}. Factor VIII/von Willebrand protein complexes are dissociated by high ionic strength or by calcium chloride containing buffers²⁹⁻³²; factor VIII derived from plasma can be bound to von Willebrand factor-Sepharose and eluted with CaCl_2 ³³. Recombinant factor VIII bound quantitatively to such an affinity column and could be completely eluted from the column with CaCl_2 , like plasma-derived factor VIII (Fig. 5b).

The coagulant activity of plasma-derived factor VIII is increased markedly by incubation with small amounts of the serine protease thrombin³⁴⁻³⁸. Thrombin activation probably results from the cleavage of specific peptide bonds in factor VIII⁵. After activation, continued incubation with thrombin leads to further degradation of the protein with a concomitant loss of coagulant activity. Recombinant factor VIII is affected by thrombin in a similar manner. The coagulation activity of the affinity purified protein from 62.2 cells was stimulated initially more than 40-fold by thrombin treatment (Fig. 6a). After longer incubation with thrombin, the activity substantially decreased (Fig. 6a). Plasma-derived factor VIII has also been shown to be inactivated by activated protein C^{34,39}, a vitamin K-dependent serine protease found in plasma, possibly functioning as a physiological regulator of coagulation. Incubation of the affinity purified 62.2 factor VIII with activated protein C resulted in the rapid loss of coagulation activity, as expected (Fig. 6b).

Conclusions

We have demonstrated by several criteria that the DNA sequences isolated here encode human factor VIII. Thus, genomic blots of male and 4X DNA hybridize with the 1:4 ratio expected for an X-linked gene. Moreover, the amino acid sequence derived from factor VIII preparations and the primary structure of the protein predicted by the cloned sequence are essentially identical⁵. Indeed, purified factor VIII preparations from plasma usually consist of a set of fragments between M_r 90,000 and 210,000 with very similar tryptic peptide maps and another, with M_r of 80,000, with a distinct map. Comparison of tryptic peptide sequences obtained from both classes of plasma-derived polypeptides⁵ with the DNA sequence of the cloned gene demonstrates that the M_r 210,000 and 80,000 polypeptides represent the N-terminal and C-terminal portions, respectively, of a single 2,332 amino acid mature polypeptide gene product. This protein presumably corresponds to the non-reducible M_r 330,000 species observed in purified factor VIII preparations⁴. The discrepancy between the molecular mass of single-chain plasma-derived factor VIII and that calculated for the cloned protein may be accounted for by the 25 potential

asparagine-linked glycosylation sites predicted by the latter. The peak of factor VIII activity found upon thrombin incubation correlates with the enhanced presence of the M_r 90,000 and a 70,000 fragment²¹. We have demonstrated that the 90,000 fragment corresponds to the amino terminal portion of the full-length molecule, that it derives from carboxy-terminal cleavage of the 210,000 fragment and that it contains the A1 and A2 repeated domains. The 70,000 species derives from the carboxy-terminus of the molecule following cleavage of the 80,000 fragment, including the A3, C1 and C2 domains⁵. Thus, removal of the unique B domain which connects the 90,000 and 80,000 fragments is associated with activation of the protein.

The recombinant factor VIII from the supernatants of cells transfected with the reconstructed gene corrects the coagulation defect of factor VIII-deficient plasma. A more stringent test of the recombinant protein was provided by the 'Coatest' assay, which measures the ability of factor VIII to accelerate the rate at which factor IXa proteolytically activates factor X in part of the intrinsic pathway of blood coagulation. The ability of several antibodies directed against factor VIII to neutralize these activities rules out the possibility that the cloned protein corresponds to other factors, such as the tissue factor/factor VII complex of the extrinsic coagulation pathway, also known to activate factor X.

It is anticipated that the availability of recombinant factor VIII from serum-free cell supernatants will further aid the study of structural modifications made on factor VIII by other components of the coagulation cascade. Such studies will be facilitated by the opportunity to create alterations in the structure, processing and activity of factor VIII by *in vitro* mutagenesis and heterologous expression of the cloned DNA sequences. Moreover, it is hoped that recombinant factor VIII will provide a safer and more plentiful therapy for individuals afflicted with haemophilia A.

We thank D. Hansen, B. Baer, U. Edman, T. Goralka, A. Kleiss, D. Leung, B. O'Connor and J. Souder for contributing to the work described here. Identification of cell line producing factor VIII RNA, cloning and assembly of factor VIII cDNA was performed by D. Capon. We also thank Genentech's Assay Development Group, Monoclonal Antibody Laboratory and the Organic Chemistry Laboratory. We appreciate the helpful discussions and continued support of D. Goeddel, A. Levinson, D. Martin, A. Ullrich, G. Hooper and R. Swanson and thank J. Arch and A. Gray for preparing the manuscript and figures. This work was supported by Genentech, Inc. and Speywood Laboratories Ltd.

The deduced amino acid sequence of human factor VIII, obtained from the DNA sequence, predicts a mature polypeptide of 2,332 amino acids containing a triplicated domain structure. The polypeptide has 35% sequence homology with the copper-binding plasma protein, ceruloplasmin. Determination of the thrombin cleavage sites in plasma-derived factor VIII polypeptides allows prediction of the domains involved in the associated activation and inactivation of the protein.

PREPARATIONS of factor VIII/von Willebrand factor complex¹⁻¹² contain four closely related properties or activities: factor VIII coagulant activity, an antigen associated with the factor VIII coagulant activity, platelet adhesion promoting activity and an antigen precipitated by antisera raised against the purified complex (factor VIII-related protein). Factor VIII separated from the complex has associated trace amounts of protein, is unstable and consists of multiple polypeptide chains¹³⁻¹⁷, hindering detailed characterization studies.

The purification of human factor VIII by affinity to a monoclonal antibody directed against the coagulant activity of factor VIII¹⁸, has allowed characterization of the protein fragments of factor VIII or thrombin-activated factor VIII by partial amino acid sequence analysis. This sequence information has been used to isolate cDNA and genomic clones encoding human factor VIII^{19,20}. The protein sequence deduced from these clones, together with an analysis of the cleavage products associated with the activation of factor VIII by thrombin, allows the assignment of thrombin cleavage sites and the identification of most of the polypeptide fragments present in highly purified factor VIII preparations. The factor VIII sequence exhibits striking homology with the plasma copper-binding protein ceruloplasmin, suggesting novel biochemical activities for factor VIII as well as a role for metal ions other than calcium in the blood coagulation cascade.

Analysis of plasma factor VIII

Preparations of human factor VIII¹⁸ purified over 300,000-fold from plasma contained several proteins of relative molecular mass (M_r) 210,000-80,000 (Fig. 1A). These protein bands were not connected by disulphide links because samples analysed under non-reducing conditions gave a similar pattern (data not shown). To determine the relationship of these multiple polypeptide chains, we analysed them by tryptic peptide mapping. The preparation used in Fig. 1B contained a protein of M_r 240,000, producing a peptide map which did not show identity with the other proteins of the mixture (Fig. 1B, a), and has been found to be a von Willebrand factor subunit (data not shown). Peptides of M_r 90,000-210,000 all had a common tryptic map, indicating that they are derived from the same or closely related polypeptide chains (Fig. 1B, b-f). Furthermore, Western blot analysis of the factor VIII preparations demonstrated that a factor VIII-specific monoclonal antibody¹⁸ reacted with the M_r 90,000-

210,000 polypeptides (data not shown). Two very similar patterns generated by the proteins of M_r 80,000 and 70,000 had a different peptide map (Fig. 1B, g, h). These results demonstrate that the fragments of M_r 90,000-210,000 are structurally related and could be pooled and treated as one polypeptide chain. The protein represented by the band of M_r 80,000 (and 70,000 when present) was analysed separately.

The purified factor VIII preparations were fractionated by gel filtration on a TSK 4000SW HPLC column; analysis of the resulting fractions demonstrated the effective separation of M_r 240,000 protein, the polypeptides of M_r 90,000-210,000 and the M_r 80,000 fragment (Fig. 2B). We performed amino acid sequence analysis on peptides generated from the M_r 80,000 protein, the polypeptide pool of M_r 90,000-210,000 and a fragment of M_r 90,000 from limited thrombin digestion of the M_r 90,000-210,000 pool. After digestion of each sample with trypsin, the resulting peptides were separated by reverse-phase HPLC and sequenced. The peptide sequence AWAYFSDVDLEK, used to prepare synthetic DNA probes identifying factor VIII genomic DNA clones, is indicated in Fig. 2C.

Structure of factor VIII protein

The molecular cloning of the entire factor VIII coding region is described in an accompanying paper¹⁹. The 2,351-amino acid sequence for factor VIII, deduced from the nucleotide sequence of these clones, is shown in Fig. 3. The first 19 amino acids of the sequence comprise the signal sequence for factor VIII, based on peptide sequence analysis of a fragment derived from the M_r 90,000-210,000 polypeptide pool. The N-terminal sequence of this M_r 30,000 fragment, obtained as a thrombin digest product of the M_r 90,000-210,000 pool, is identical to the first 12 amino acids which follow the predicted factor VIII leader sequence (see Fig. 5). This presequence exhibits a core of 10 hydrophobic amino acids flanked by two charged residues, a structure which conforms to that observed for the leader sequences found in most secreted proteins²¹. The mature protein contains 2,332 amino acids (calculated M_r 264,763).

The availability of the complete factor VIII sequence reveals the organization and identity of the tryptic peptides obtained from the pools of separated plasma-derived factor VIII fragments. Essentially all tryptic peptide sequences determined from the M_r 90,000-210,000 protein pools are located in the amino-

Fig. 1 A, Purified human factor VIII analysed by SDS-polyacrylamide gel electrophoresis. B, Two-dimensional tryptic mapping of factor VIII polypeptide chains. The resulting tryptic patterns of proteins of M_r : a, 240,000; b, 210,000; c, 170,000; d, 150,000; e, 120,000; f, 100,000; g, 80,000; and h, 70,000 are shown.

Methods: The purified protein¹⁸ was reduced and analysed in a 5–10% polyacrylamide gradient gel in the presence of SDS by the procedure of Laemmli³⁷. The molecular weights of the protein standards are shown (myosin, β -galactosidase, phosphorylase B, bovine serum albumin and ovalbumin). The bands were detected using the silver stain procedure of Morrissey³⁸. 1 μ g of a factor VIII preparation was denatured in 1% SDS and labelled with 300 μ Ci ^{125} I for 15 min using the iodobead procedure³⁸. Labelled polypeptides were located on dried SDS-polyacrylamide gels by autoradiography and digested by incubation of gel slices with 10 μ g trypsin in 0.1 M ammonium bicarbonate buffer for 6 h at 37°C. After repeated lyophilizations, peptides were dissolved in 8.8% formic acid and a portion was subjected to thin-layer electrophoresis in the same buffer (400 V for 45 min) on pre-coated TLC-cellulose platters (E. Merck, Darmstadt, FRG). For the second dimension, peptides were separated by ascending chromatography in *n*-butanol/pyridine/glacial acetic acid/water, 75:50:15:60 (v/v). The plates were then subjected to autoradiography.

terminal half of the molecule, whereas those sequences obtained for the M_r 80,000 fragment are found at the carboxy-terminus of the factor VIII sequence (unpublished results). The most carboxy-terminal tryptic peptides identified for the M_r 90,000–210,000 pool gave the sequences GEFT and –QEE, beginning at positions 1,155 and 1,194, respectively. This shows that the M_r 210,000 fragment consists of a protein of $M_r \geq 135,000$ containing 14 potential asparagine-linked glycosylation sites. The location of the M_r 80,000 fragment of factor VIII is delineated by two peptide sequences which define a stretch of ~680 amino acids. The first of these was obtained from the amino-terminal sequence of the M_r 80,000 fragment beginning at position 1,649 (see Fig. 5), whereas the second corresponds to a tryptic peptide, MEVLGCEAQDL, 12 amino acids from the C-terminus predicted by the DNA sequence. Thus, there is no significant removal of C-terminal sequences from the plasma-derived molecule. The failure to recover tryptic peptide sequences from the region between position 1,200 and the M_r 80,000 fragment is probably due to the relatively low concentration of the M_r 210,000 species in the M_r 90,000–210,000 fragment pool. This position should therefore be considered the minimal C-terminal extent of the M_r 210,000 protein.

Computer-aided analysis of the factor VIII protein sequence revealed two types of internal homology: the first consists of a triplicated segment (A domain) found at positions 1–329, 380–711 and 1,649–2,019 of the mature polypeptide (Fig. 4); the second and third domains of the triplication are separated by a region of 983 amino acids (B domain) extremely rich in potential asparagine-linked glycosylation sites. In addition, an unrelated duplication of 150 amino acids is found at the C-terminus of the molecule (C domain). The A domains have ~30% amino acid homology, whereas the C domains are ~40% homologous. Most

Fig. 2 Purification of factor VIII polypeptides. A, Fractionation of proteins by TSK 4000 HPLC. B, SDS-polyacrylamide gel analysis of fractions from TSK 4000 chromatography. C, Reverse-phase HPLC separation of tryptic peptides of M_r 80,000 protein.

Methods: A, Human factor VIII preparations¹⁸ were dialysed into 1% ammonium bicarbonate containing 0.1% SDS. The samples were lyophilized and stored at –20°C until use. The samples were reconstituted in distilled water and applied to a TSK 4000 SW column (0.75 $\times$ 50 cm; Alltech Associates, Deerfield, Illinois) equilibrated with 0.1 M sodium phosphate buffer, pH 7.0, containing 0.1% SDS. Samples of ~0.15–0.25 ml were injected and the column developed isocratically at a flow rate of 0.5 ml min^{–1}. Absorbance was monitored at either 206 nm or 280 nm and fractions (0.2 ml) collected. Fractions across the profile were reduced and analysed by SDS-polyacrylamide gel electrophoresis as described in Fig. 1 legend. The protein of M_r 80,000 was pooled for tryptic digestion as shown in A. C, The TSK 4000 SW purified protein of M_r 80,000 (0.8 nM) was dialysed under a nitrogen atmosphere overnight against 0.36 M Tris-HCl, pH 8.6, containing 8 M urea, 3.3 mM EDTA and 10 mM dithiothreitol, DTT (final vol. 1.5 ml). The protein was alkylated by adding 15 μ l of 5 M iodoacetic acid (dissolved in 1 M NaOH). The reaction was allowed to proceed for 35 min at room temperature in the dark and was quenched by adding DTT to a final concentration of 100 mM. The protein solution was dialysed against 8 M urea in 0.1 M ammonium bicarbonate for 4 h. The urea dialysis solution was changed over a period of 24 h to gradually reduce the urea concentration to a final level of 0.5 M. Trypsin was added at a weight ratio of 1:50 at 37°C for 12 h. HPLC separation of the resulting tryptic peptides was performed on a high-resolution Synchropak RP-P C-18 column (0.46 $\times$ 25 cm; 10 μ). The column was developed with a gradient of acetonitrile (1–70% in 200 min) in 0.1% trifluoroacetic acid. Absorbance was monitored at 210 nm and 280 nm. Each peak was collected and stored at 4°C until subjected to sequence analysis in a Beckman spinning cup sequencer with on-line phenylthiohydantoin amino acid identification⁴⁰. The arrow identifies the peptide (AWAYFSDVDLEK) resulting in identification of a factor VIII genomic clone^{19,20}.

Ceruloplasmin contains six copper atoms in three distinct types of coordination: two of type 1, one of type 2 and three electron paramagnetic resonance-nondetectable type 3 copper ions²⁶. The type 1 copper ions are thought to bind to the carboxy-terminal portion of the domains of ceruloplasmin (domain residues 240–350; Fig. 4) based on sequence homology with the type 1 copper-binding protein plastocyanin²⁷. The four amino acid side chains proposed as the ligands for the type 1

Fig. 4 Domain homology of human factor VIII and human ceruloplasmin²². Identical residues in four of the six domains are boxed. The protein is indicated to the left of the lines (VIII, factor VIII; Cp, ceruloplasmin) with the associated number indicating the position in the sequence of the first amino acid of the line. A domain residue numbering system is shown above the sequences. * Residues believed to be the ligands for type 1 copper (based on homology to plastocyanin²⁷).

copper atoms of ceruloplasmin are found in the first and third A domains of factor VIII (histidines 287 and 338, cysteine 333 and methionine 343; see Fig. 4). The conservation of the copper-ligand residues found in ceruloplasmin strongly suggests similar metal binding characteristics for factor VIII.

Thrombin cleavage

The coagulant activity of factor VIII is increased markedly by treatment with catalytic amounts of the serine protease thrombin²⁸. Thrombin activation of factor VIII is associated with a series of polypeptide cleavages¹³⁻¹⁷. Further incubation with thrombin leads to degradation of the protein with a concomitant loss of coagulant activity¹³⁻¹⁷. To understand the structural basis for these observations, the separated pools of factor VIII fragments were subjected to thrombin digestion and the resulting products characterized by SDS-polyacrylamide gel electrophoresis. Thrombin digestion of the *M*_r 80,000 protein resulted in a product of *M*_r 73,000 (Fig. 5A). Treatment of the polypeptide pool of *M*_r 90,000-210,000 led initially to the appearance of two bands of *M*_r 43,000 and 50,000 (Fig. 5A). Longer incubation with thrombin resulted in the conversion of the *M*_r 50,000 fragment to polypeptides of *M*_r 30,000 and 20,000 (data not shown). The *M*_r values of these thrombin digest fragments are similar to those generated by thrombin treatment of native factor VIII preparations^{13,15,16}. Amino-terminal sequence analysis was performed on the separated protein chains before and after thrombin digestion. The resulting sequences are compared with the corresponding amino acid sequences deduced from the factor VIII cDNA sequence¹⁹ in Fig. 5B; also shown are the potential cleavage sites found at the amino-terminus of the *M*_r 80,000 protein and that which separates the *M*_r 90,000 fragment from the carboxy-terminal portion of the *M*_r 210,000 protein. The sequence surrounding the latter potential cleavage site (position 740) is similar to the amino-terminal sequence of the *M*_r 70,000 protein (-PRSF---RH-) (Fig. 5B). There is no other consensus sequence that would predict the specificity of thrombin cleavage. A homologous stretch preceding the thrombin cleavage sites for the *M*_r 43,000 and 73,000 proteins is observed (Fig. 5B), but whether this homology determines thrombin specificity or simply reflects the internal duplication is uncertain. The most consistent sequence found at thrombin cleavage sites within factor VIII is an arginine residue followed by either serine or alanine. Other such sequences (-RS- or -RA-) do occur within the protein but are not cleaved, suggesting the possible involvement of secondary structure in thrombin specificity. The cleavage that frees the *M*_r 80,000 protein occurs at an arginine-glutamic acid sequence, probably not a thrombin-generated cleavage site. This cleavage occurs

quickly and is complete within the time required for isolation of the protein. The precursor factor VIII protein therefore may be cleaved to free the *M*_r 80,000 polypeptide by a protease other than thrombin.

Discussion

The structure of factor VIII revealed by the amino acid sequence predicted from the cloned cDNA and the structural characterization of polypeptide fragments described here are summarized in Fig. 6. The size of the factor VIII precursor moiety is consistent with the reported isolation of single-chain *M*_r 330,000 protein from plasma¹⁸ and supports the notion that the protein circulates as a high-molecular weight form that is readily cleaved in plasma and/or during isolation to a series of degradation products.

The primary structure of factor VIII exhibits three distinct types of structural domain, including a triplicated region of ~330 amino acids (A domains), a unique region of 980 amino acids (the B domain) and a carboxy-terminal duplicated region of 150 amino acids (C domains), which are arranged in the order A1-A2-B-A3-C1-C2 (Fig. 6). The A domains of factor VIII show significant homology to ceruloplasmin, consisting also of a triplicated structure of three A domains but lacking both B and C domains²²⁻²⁴. Particularly striking is the clustering of cysteine residues at similar locations within related structural domains of factor VIII (Fig. 6). The determination of disulphide pairings for ceruloplasmin^{23,29} predicts two types of internal disulphide bonding arrangements for the A domains of factor VIII. The disulphide structure proposed for the C domains of factor VIII is based on the proposition that the disulphide linkages form between the two cysteine residues found in each domain. The large B domain which separates the second and third A domains of factor VIII contains only four cysteine residues, but the presence of 19 asparagine-linked glycosylation sites suggests that this region is extensively modified by carbohydrate addition.

The activation of factor X by factor IX_a in conjunction with factor VIII is known to require calcium ions. Factor IX_a and factor X both contain γ-carboxyglutamic acid residues which are thought to be involved in calcium binding. The protein-bound calcium ions mediate the interaction of these proteins with the phospholipid surface. The homology of factor VIII with ceruloplasmin suggests the possible involvement of copper or other metal ions in the role of factor VIII in factor X activation. One possibility for the role of such metal ion involvement is suggested by the binding of lanthanide ions by γ-carboxyglutamic acid residues³⁰. It is interesting to speculate that the potential copper-binding ligands of factor VIII interact with a metal ion jointly bound by the γ-carboxyglutamate

Fig. 5 A, Thrombin cleavage of separated factor VIII polypeptide fractions. B, Alignment of thrombin-generated amino termini with the deduced amino acid sequence¹⁹.

Methods: A, The factor VIII polypeptides were separated as described in legend to Fig. 2A. SDS was removed by dialysis of the fractions against 8 M urea solutions and urea removed by dialysis against 0.01 M Tris, pH 8.0. Thrombin was then added at weight ratios to a maximum of 1:20. The digestions were allowed to proceed at room temperature and the extent of cleavage was monitored by SDS-gel electrophoresis. Lanes 1 and 2 are the M_r 80,000 protein with and without thrombin, respectively; lanes 3 and 4 are the M_r 90,000–210,000 protein without and with thrombin, respectively. B, Thrombin digestion products were separated by preparative SDS-gel electrophoresis, electroeluted by the procedure of Hunkapiller *et al.*⁴¹ and analysed on a Beckman spinning cup sequencer⁴⁰. The M_r 80,000 protein was obtained by TSK separation as described for Fig. 2A. The thrombin cleavage site is indicated by a space in the cDNA deduced sequence. The number above the subsequent amino acid corresponds to the position of that residue in the linear sequence. The amino-terminal protein sequences for the various polypeptide chains are aligned under the translated gene sequence. —, Positions where no residue could be identified; X, positions where the wrong amino acid was determined. The relative molecular masses of the proteins separated are listed (30K is the amino terminus obtained for the gel-eluted polypeptide with a M_r of 30,000); solidi indicate cleavage products (for example, 50/43 indicates the cleavage which separates the M_r 50,000 and 43,000 species). Regions which share sequence homology are boxed.

residues of factors IX or X. In addition to copper transport and haemostasis, several enzymatic functions have been ascribed to ceruloplasmin, including ferroxidase activity, amino oxidase activity and superoxide dismutase activity^{31–35}. It will be important to determine whether any of these activities are associated with factor VIII.

The amino-terminal sequence of factor VIII thrombin fragments and the homology of factor VIII with ceruloplasmin provide insight into a functional purpose for the cleavages. Factor VIII isolated from plasma is usually degraded. In certain preparations, small amounts of a M_r 330,000 protein were observed when analysed on SDS-polyacrylamide gels run under non-reducing conditions; this protein was not observed when the factor VIII samples were reduced before electrophoresis. This reducible 330,000 may be a disulphide-linked, limited pro-

termini) from a single-chain circulating form. By analogy with factor V, the M_r 90,000 and 80,000 proteins would correspond to fragments D and E of factor V, respectively³⁴. These two fragments of factor V can be separated from the activation peptides and isolated as a functional two-subunit protein^{35,36}. Both subunits are required for factor V activity³⁵ and both may be required for factor VIII activity. A highly glycosylated intermediate region is cleaved from both proteins. Therefore, both factors V and VIII seem to be highly similar in structure, thrombin cleavage pattern and, presumably, function.

The studies described here provide a structural basis for defining the role of the diverse molecular forms of factor VIII in their interaction with other proteins of the coagulation cascade. The availability of complete factor VIII cDNA clones

capable of programming recombinant factor VIII synthesis in mammalian cell cultures¹⁹ will offer a unique opportunity to perform similar studies with the single-chain precursor molecule. The questions raised here concerning the relationship of processing events, structural domains and homology to ceruloplasmin with the biological function of factor VIII may be answered by studying structural changes introduced into the protein by modification of these cloned DNA sequences.

We acknowledge the support of Speywood Laboratories Ltd. We thank Dr John Bell, Alice Kleiss and William Henzel for laboratory assistance; Gary Hooper for his assistance in the coordination of the project between various groups and companies; and Robert A. Swanson and Dr David W. Martin Jr for their encouragement.

A complete copy of the mRNA sequences encoding human coagulation factor VIII:C has been cloned and expressed. The DNA sequence predicts a single chain precursor of 2,351 amino acids with a relative molecular mass (M_r) 267,039. The protein has an obvious domain structure, contains sequence repeats and is structurally related to factor V and ceruloplasmin.

HAEMOPHILIA A is a bleeding disorder caused by deficiency or abnormality of a particular clotting protein, factor VIII:C¹ occurring in about 10-20 males in every 100,000. Afflicted individuals suffer episodes of uncontrolled bleeding and are treated currently with concentrates rich in factor VIII:C derived from human plasma. The available therapy, although reasonably effective, is very costly and is associated with a finite risk of infections. We report here significant progress in the use of recombinant DNA technology to provide pure human factor VIII:C as an alternative treatment for haemophiliacs.

Blood clotting begins with injury to a blood vessel. The damaged vessel wall causes adherence and accumulation of platelets activating the plasma proteins which initiate the coagulation process. Sequential activation, via specific proteolytic cleavages and conformational changes, of a series of proteins comprising the coagulation cascade eventually leads to deposi-

tion of insoluble fibrin which, together with aggregated platelets, curtails the escape of blood through the damaged vessel wall. Factor VIII:C is a large plasma glycoprotein that functions in the blood coagulation cascade as the cofactor for the factor IXa-dependent activation of factor X. It can be activated proteolytically by a variety of coagulation enzymes including thrombin².

In order to provide factor VIII:C for treatment of haemophiliacs we cloned a full-length cDNA. A major obstacle to the cloning effort was the large size of the protein, estimated to be at least M_r 250,000. Purification of factor VIII:C from plasma³ is made difficult by its low abundance, its extreme sensitivity to degradation by serum proteases and its tight association with polymeric forms of the more abundant protein, von Willebrand factor. Fass *et al.*⁴ have described a purification procedure for porcine factor VIII:C using monoclonal antibody

Fig. 1 *a, b*; N-terminal amino acid sequence analysis of bovine thrombin cleavage and natural cleavage fragments of porcine factor VIII:C. *c*, The positions of fragments in the factor VIII:C precursor in diagrammatic form. The molecular masses are the apparent porcine values deduced from SDS gel electrophoresis rather than those calculated from the human amino acid sequence. Map lengths are indicated in amino acid residues to correlate with Fig. 4. In *a*, N-terminal sequences were determined for the indicated fragments of porcine factor VIII:C. The first residue in each sequence could not be assigned and is indicated as ? In *b*, the porcine amino acid sequences are compared with the corresponding sequences in human factor VIII:C predicted from the nucleotide sequence of the cDNA clone (Fig. 4). Boxed areas, identity between sequences. Thrombin cleavage fragments of porcine factor VIII:C were purified by SDS polyacrylamide gel electrophoresis and located in the unfixed gel using a small portion of ^{125}I -labelled porcine factor VIII:C as a tracer. After electrophoretic elution from the gel matrix as described previously²⁸, the polypeptide sample was subjected to N-terminal amino acid sequence analysis using an Applied Biosystems gas-phase sequencer¹¹.

immunoaffinity chromatography, obtaining highly purified polypeptides of M_r 160,000, 130,000 and 76,000, similar in size to human factor VIII:C polypeptides⁵. Although it has been generally supposed that factor VIII:C, like its homologue factor V, is synthesized as a single chain macromolecular precursor which is then cleaved to yield the fragments found in purified preparations, the results presented here are the first conclusive demonstration that this supposition is correct⁶.

Additional obstacles to the isolation of a factor VIII:C cDNA clone were the lack of a cell line which made factor VIII:C and uncertainty about its site of synthesis *in vivo*⁷⁻⁹. Microsequencing of highly purified porcine factor VIII:C yielded sufficient amino acid sequence to construct oligonucleotide probes. We used these probes to identify a partial clone by direct screening of porcine genomic DNA libraries. The clone provided a probe for identification by cross-species homology of a corresponding human genomic clone. Using this probe, we determined that human liver is a source of factor VIII:C mRNA and obtained subsequently from such tissue the entire 9 kilobase (kb) cDNA sequence as a set of overlapping clones. Reconstruction of these clones into one continuous sequence within an expression vector provided a functional full-length cDNA able to express active protein after transfection into mammalian cells.

Porcine factor VIII:C

Treatment of highly purified porcine factor VIII:C with bovine thrombin (factor IIa) causes an initial activation of up to 60-fold⁴ concomitant with loss of the M_r ~160,000 polypeptide, transient appearance of a M_r 130,000 and the appearance of a new chain of M_r 82,000 (Fig. 1c). As the digestion proceeds, the M_r 76,000 polypeptide generates a fragment of M_r 69,000 and the M_r 82,000 polypeptide is cleaved, apparently to yield polypeptides of M_r ~50,000 and 40,000.

Our sequence analysis was performed using factor VIII:C purified from ~101 of porcine plasma collected from about ten hogs with precautions to minimize proteolysis during collection and subsequent processing¹⁰. We prepared 0.1–1.5 nmol of each of the M_r 160,000, 130,000 and 76,000 chains originally present in purified porcine factor VIII:C and the 82,000, 69,000,

50,000 and 40,000 thrombin cleavage fragments. N-terminal amino acid sequence analysis using the microsequencing procedures described previously¹¹ yielded the data presented in Fig. 1a, b. The M_r 160,000, 130,000, 82,000 and 50,000 chains have the same N-terminal amino acid sequence for at least thirty residues, whereas the 69,000 and 40,000 fragments have distinct N-terminal sequences. There is, however, striking homology between the 69,000, 40,000 and the 160,000 polypeptides and their fragments. The M_r 76,000 fragment shows no N-terminal sequence homology with the N-terminal sequences of any of the other fragments. Comparison of these sequences with partial sequence data for bovine factor V has led to a hypothetical model for the structural relationship between the putative single chain factor VIII:C and its cleavage products⁶ similar to that shown diagrammatically in Fig. 1c.

Genomic cloning

As the tissue source of mRNA for factor VIII:C was unknown, we tried the novel approach of directly screening genomic libraries with oligonucleotide mixtures to obtain a unique length of porcine factor VIII:C DNA. We used two probes, one a pool of long oligomers containing few sequences and the other a pool of shorter oligomers containing all possible sequences. We identified residues His8–Met22 of the M_r 69,000 chain (see Fig. 1) as containing the least codon ambiguity. The set of 45-mers described in the legend to Fig. 2 was selected on the basis of eukaryotic codon usage¹², the relative stability of G·T versus A·C mismatches¹³ and the infrequency of the dinucleotide CpG in eukaryotic genes. Jaye *et al.*¹⁴ used a similar strategy to generate long oligonucleotides for screening a cDNA library, but they did not attempt genomic screening. A set of 15-mers containing all possible sequences that could encode the Trp18–Met22 region of the M_r 69,000 polypeptide served as the secondary probe.

We constructed a genomic library from *Bam*HI digested female porcine DNA and screened it with the radiolabelled 45-mers under relatively nonstringent conditions (see Fig. 2 legend). Rescreening the library with the 15-mers yielded four clones out of 4×10^5 recombinants which hybridized strongly to

both the 45-mers and the 15-mers. The four bacteriophages were isolated and, on hybridization to additional oligonucleotides derived from the amino acid sequence of the M_r 69,000 polypeptide, one contained a 6.6 kilobase (kb) *Bam*HI fragment that hybridized to all probes (Fig. 2). Sequence analysis of DNA fragments subcloned into M13 confirmed that we had isolated a recombinant containing DNA, encoding a portion of the M_r 69,000 polypeptide. The 45-mer had 11% mismatch (5 of 45 nucleotide positions) but still hybridized strongly to the porcine genomic clone.

To obtain a human factor VIII:C genomic clone, the 6.6 kb *Bam*HI fragment from the porcine genomic clone was used to screen a human *Hae*III/*Alu*I library¹⁵. From 8×10^5 screened, a single recombinant phage containing an insert of about 16 kb was isolated (Fig. 2). The region of this clone containing sequence homologous to the porcine M_r 69,000 fragment, identified by hybridization to the 45-mers, was subcloned into M13 and its sequence determined. The sequence shows strong (>80%) homology to the porcine factor VIII:C sequence at both the nucleotide and derived amino acid level (see Fig. 1). Additionally, an exon/intron boundary occurs at precisely the same position in both porcine and human genomic DNAs.

To confirm further that we had cloned a segment of the human factor VIII:C gene, we demonstrated linkage to the X chromosome by comparing the Southern blot band intensities between human male diploid DNA and XXXXY DNA (human lymphoblastoid line GM 1202A from the NIGMS mutant cell repository). Several unique DNA fragments from the human genomic clone were used as probes. Each hybridized to a single human fragment which was appropriately overrepresented in the 4X DNA when compared with human albumin DNA internal controls.

The entire human factor VIII:C gene was isolated subsequently as overlapping clones spanning ~200 kb. We thus constructed a genomic library from the human XXXXY cell line and screened sequentially with unique probes from the ends of previously isolated recombinants. The factor VIII:C gene spans more than 180 kb; most of its exons are small (150–250 base pairs) with the exception of the 3.1 kb exon (Fig. 2) and the 1.9 kb 3'-most exon, which includes 1.8 kb of non-coding sequence.

Table 1 Expression of factor VIII:C cDNA in COS-7 cells

	Chromogenic activity (mU ml ⁻¹)	1 stage APTT assay (mU ml ⁻¹)
No DNA	<0.05	<<
pCVSVL	<0.05	<<
pCVSVL-VIII	7	10.0
+ thrombin	ND	50
+ α VIII IgG	<0.05	ND

The full-length cDNA clone was excised from pSP64-VIII with *Sal*I and inserted into the *Pst*I site in pCVSVL¹⁸ by addition to the vector of synthetic oligonucleotide adapters containing *Sal*I cohesive ends. The resulting plasmid containing the factor VIII:C cDNA in the correct orientation for transcription from the adenovirus major late promoter was designated pCVSVL-VIII. Plasmid DNA (8 μ g) was transfected into COS-1 monkey cells²³ in a 10 cm dish by the DEAE-dextran transfection protocol²⁴ with the addition of chloroquin treatment²⁵. The transfected cells were incubated for 36 h, then rinsed and fed with 4 ml serum-free media. Samples were taken for assay 24 h later. Factor VIII:C activity was determined by the Kabi Coatest factor VIII:C method modified to afford a sensitivity better than 0.05 mU ml⁻¹ and by the one-stage activated partial thromboplastin time (APTT) coagulation assay²⁶ using factor VIII:C-deficient plasma. For thrombin activation, samples were pretreated 1–10 min with 0.2 units ml⁻¹ thrombin at room temperature. The peak of activity (value shown) was reached after 4 min and then gradually declined. Inhibition with anti-factor VIII:C immunoglobulin was measured by the standard Bethesda protocol²⁷. Isolated immunoglobulin from serum of a patient with high titre factor VIII:C inhibitor was prepared by ion exchange and protein A Sepharose chromatography¹⁰. ND, not determined; <<, not detectable.

cDNA cloning

Our original human factor VIII:C genomic clone provided a probe with which to identify a useful tissue source for human factor VIII:C mRNA. A cell line secreting factor VIII:C is not available, but it had been reported that the protein was synthesized in liver and spleen^{7–9}. RNA blot analysis, initially with porcine material, confirmed the presence of very low mRNA levels in these tissues. Northern blot analysis of human liver mRNA, using a highly radioactive single-stranded probe of ~800 nucleotides of human factor VIII:C exon DNA (see Fig. 3 legend), demonstrated a single mRNA of ~9 kb (Fig. 3A, lanes a, b). A messenger of this size could encode a single-chain factor VIII:C precursor of M_r 250,000–300,000. In other experiments, the same size mRNA was detected in placenta but was absent from peripheral blood lymphocytes. All of these observations are consistent with the suggestion that factor VIII:C mRNA is synthesized by endothelial cells¹⁶.

We demonstrate in Fig. 3A (lane c) that the level of factor VIII:C mRNA in human liver is far lower than that of coagulation factor IX mRNA. Quantitative RNA dot blot hybridizations indicated that the amount of factor VIII:C mRNA was 20–40 times lower than factor IX mRNA. We had found previously that 1 in 5,000 recombinant phage in a liver cDNA library contains factor IX sequences. Thus we estimate that libraries of more than 200,000 recombinants would be required to isolate a single factor VIII:C clone.

Several large cDNA libraries were constructed in λ Charon 21A and GT10 (see Fig. 3 legend), using as a first strand primer either oligo(dT) or a unique 38-mer deduced from the sequence of the large human exon in Fig. 2. Ten factor VIII:C cDNA clones were isolated after screening ~2,000,000 recombinants

Fig. 2 a, Porcine and b, human factor VIII:C genomic clones. Homologous 3.1 kb exons are indicated by shaded boxes.

Methods: A porcine genomic library was constructed from *Bam*HI

digested female porcine liver DNA in the bacteriophage vector λ J1 (a derivative of L47.1) using established procedures. Recombinants (4×10^5) were screened using a modification of the procedure of Woo²⁹. A set of 45-mers containing the sequences 5'd (CATGCCATA^ATCCCACAGCTG^TTCCACAGCAGCAAT^AAGTAGTG) was synthesized on the Applied Biosystems Model 380A instrument. Filters were hybridized with 5×10^6 c.p.m. ml⁻¹ (0.5 pmole ml⁻¹) of ³²P-labelled 45-mers for 12 h at 45 °C in 5X SSC, 5X Denhardt's, 0.1% SDS, 100 μ g ml⁻¹ denatured salmon sperm DNA. Filters were washed at 50 °C in 5X SSC, 0.1% SDS, air dried and subjected to autoradiography using Kodak XAR film. After autoradiography, filters were denatured in 0.1M NaOH, neutralized and rehybridized with ³²P-labelled 15-mers, sequence 5'd (CATNCC^ATA^ATCCCA). Hybridization was performed as described above at 37 °C. Recombinants hybridizing to both oligomers were plaque purified and phage DNA prepared. Phage DNA prepared from one recombinant (PB34) contained a 6.6 kb *Bam*HI fragment which hybridized strongly to both sets of oligonucleotides in Southern blot analysis. The 6.6 kb *Bam*HI insert was purified from an agarose gel and ³²P-labelled by nick translation. Recombinants (8×10^5) from the human *Hae*III/*Alu*I genomic library of Lawn *et al.*¹⁵ were hybridized with 10^6 c.p.m. ml⁻¹ of the nick-translated porcine probe using the same conditions described for the 45-mer hybridization. A single recombinant phage, HH25, was thus isolated. *Sau*3A fragments of the insert from HH25 were subcloned into M13 and a phage which hybridized to the radio-labelled 45-mer was identified. The sequence of the *Sau*3A fragment in this subclone proved that HH25 contained DNA from the human factor VIII:C gene. The entire exon (shaded box) was subsequently sequenced. A 0.8 kb *Bam*HI fragment spanning the 3' exon/intron junction was subcloned as the probe to screen for a tissue source of factor VIII:C mRNA (see Fig. 3).

from the oligo(dT) libraries; 55 additional cDNA clones were obtained from among 1,000,000 recombinants from the 38-mer primed library. Four of the several clones characterized in detail are illustrated in Fig. 3B together spanning 9,000 base pairs (bp), sufficient to encode the entire mRNA detected by Northern

Fig. 3 A, Northern blot analysis to locate a tissue source for human factor VIII:C mRNA. Polyadenylated RNA (5 µg) extracted³⁰ from adult liver (lane a) or fetal liver (lanes b, c) was fractionated on an 0.8% agarose formaldehyde gel and transferred to nitrocellulose as described³¹. The filter in lanes a, b was hybridized with 5×10^6 c.p.m. of a ^{32} P-labelled factor VIII:C single-stranded probe prepared by primed synthesis from an M13 template which contained an 0.8 kb base *Bam*HI fragment of HH25 (see Fig. 2 legend)^{32,33}. The filter in lane c was probed in the same manner except 5×10^6 c.p.m. of a human factor IX probe of identical specific activity was used in addition. The exposure time for lanes a, b was longer than that for lane c and the RNA was from a different preparation. B, restriction map (*Eco*RI) of the human factor VIII:C cDNA sequence showing the single long open reading frame as a shaded box. An illustrative set of four overlapping bacteriophage λ clones are shown. Those designated dT4, dT51 and dT11 were from oligo(dT) primed λ Charon 21A libraries. Clone PE31 was from a library in λ GT10 primed with a unique 38-mer (solid rectangle). The cDNA sequence comprises 150 bases of 5'-untranslated region, an open reading frame of 7,053 bases and 1,806 bases of 3'-untranslated region.

Methods: Oligo(dT) primed double-stranded cDNA was synthesized from 10 µg polyadenylated fetal liver RNA as described³⁴. 200 pmol of a unique complementary 38-mer (nucleotides 5,308–5,345) and 10 µg polyadenylated fetal liver mRNA were denatured in 10 mM CH_3HgOH . The reaction was made 140 mM in 2-mercaptoethanol, 700 mM KCl, 1 mM EDTA, 20 mM Tris-HCl (pH 8.3 at 42°C), 1 unit μl^{-1} of RNasin (Promega-Biotec) and incubated at 50°C for 2 min and at 42°C for 2 min. First and second strand synthesis was then performed as for the oligo(dT) primed cDNA³⁴. The second strand reaction was terminated by the addition of EDTA to 20 mM. The *Eco*RI sites were methylated, after the addition of S-adenosylmethionine to 50 µM and 40 units of *Eco*RI methylase, by incubation at 37°C for 1 h. These reactions were terminated by phenol-chloroform extraction and chromatographed using Sephadex G-50 equilibrated in 10 mM Tris-HCl (pH 8.0), 1 mM EDTA, 100 mM NaCl. DNA in the excluded volume was pooled and precipitated with ethanol. The double-stranded cDNA was blunted in 50 µl containing 50 mM Tris pH 8.3, 10 mM MgCl_2 , 10 mM 2-mercaptoethanol, 50 mM NaCl, 50 µM of deoxynucleotide triphosphate, 100 µg ml^{-1} ovalbumin and 5 units of T4 polymerase (PL Biochemicals). The reaction was incubated at 37°C for 30 min and then terminated by phenol-chloroform extraction. Nucleic acids were recovered by ethanol precipitation with 2 M ammonium acetate. Kinased *Eco*RI linkers (NE Biolabs; 300 ng) were then added to the blunted double stranded cDNA by ligation overnight at 16°C in a final volume of 30 µl. The reaction was diluted to 200 µl in *Eco*RI digestion buffer and digested with 300 units of *Eco*RI (NE Biolabs) for 2 h at 37°C. EDTA to 15 mM was added and the reaction extracted with phenol-chloroform and chromatographed over Sepharose CL-4B (Pharmacia) equilibrated with 10 mM Tris-HCl (pH 8.0), 1 mM EDTA, 100 mM NaCl. cDNA in the void volume was collected and precipitated by ethanol in the presence of 10 µg yeast tRNA carrier. cDNA was redissolved in 10 mM Tris-HCl (pH 8.0), 1 mM EDTA and ligated to *Eco*RI cleaved, phosphorylated, λ Charon 21A DNA for the oligo(dT) primed cDNA and to λ GT10 DNA for the primer extended cDNA. The libraries were packaged, plated and initially screened using a unique ^{32} P-labelled 53-mer (nucleotides 5,158–5,210) permitting the isolation of both PE31 and dT51. Recombinant dT4 was identified with a ^{32} P-labelled pool of 64 56-mers containing the sequences: 5'd(TCCCAATCCTCTCTTC¹GC²GA³ATATAGTG⁴ACCCA⁵GTCTT⁶GGGTGCTTCTT) (using the same criteria as was used for the construction of the 45-mer pools) made to residues (Lys3-Asp21) of the *M*_{40,000} polypeptide fragment of porcine VIII:C. Recombinant dT11 was isolated using a nick translated 3' end *Pst*I/*Eco*RI fragment (nucleotides 5,902–7,127) of dT51. Numerous other cDNA clones were isolated by similar methods; some were also characterised in detail, sequenced and used in the construction of the full-length cDNA clone. Selected cDNA and genomic exon fragments were ligated to one another two at a time, subcloned and ultimately inserted in the *Sal*I site of pSP64 after the addition of a synthetic *Sal*I site at nucleotide 145. The resulting recombinant, pSP64-VIII, contains the factor VIII:C cDNA from just before the initiator ATG (at nucleotide 150–152) to nucleotide 7,422 (some 200 bp downstream from the terminator at nucleotide 7,201).

blot analysis. (The unique 9,009 bp cDNA sequence we obtained after sequencing numerous overlapping fragments of cDNA and genomic DNA has been deposited in the NIH US Nucleic Acid Sequence Databank and is available through GENBANK.) The sequence comprises a 5'-noncoding region of 150 nucleotides, a single long open reading frame of 7,053 nucleotides (2,351 codons) and 1,806 nucleotides of the 3'-noncoding region. The translated sequence, in a single-letter amino acid code, is presented as Fig. 4.

A full-length cDNA clone was assembled (see Fig. 3 legend) and inserted into the *Sal*I site of the polylinker in plasmid pSP64 (Promega Biotec). We thus obtained a recombinant, pSP64-VIII, with a single continuous factor VIII:C coding sequence that could be readily excised by *Sal*I digestion for insertion into a variety of expression vectors.

Expression and structure

To confirm that the factor VIII:C cDNA indeed encodes active factor VIII, we introduced the full-length cDNA into the mammalian expression vector pCVSVL^{17,18}. Plasmid pCVSVL-VIII contains the cDNA in the proper orientation to be expressed from the adenovirus major late promoter. Medium collected 60 h after transfection of COS-1 cells with this plasmid contained readily detectable levels of factor VIII:C activity (Table 1). No activity was detected in controls. The activity was inhibited by antibody to human factor VIII:C and was activated fivefold by thrombin.

The sequence of the cDNA clone comprises 2,351 amino acids from the initiator Met to the terminating Tyr residue and begins with a secretory leader peptide sequence of 19 amino acids. Regions of homology with the previously determined amino acid sequences of porcine factor VIII:C fragments can be located (Fig. 1), confirming the model for the structure of porcine factor VIII:C of Fass *et al.*⁶ and predicting the mature N-terminus and thrombin cleavage sites of the human molecule.

Fig. 4 Amino acid sequence of the human factor VIII:C precursor, predicted from the sequences of cDNA and genomic clones. Arrows indicate (1) a presumed signal peptidase cleavage site at residues 19–20 (Ser–Ala); (2) thrombin cleavage sites at residues 391–392, 759–760 and 1,708–1,709 (all Arg–Ser); (3) a possible thrombin cleavage site at residues 1,667–1,668 (Arg–Glu). Before each cleavage site the apparent *M_r* of the corresponding porcine factor VIII:C fragment C-terminal to the cleavage site⁶ is given. *, Amino acid residue identity with porcine factor VIII:C amino acid sequence determined from a variety of proteolytic and chemical cleavage fragments. Potential N-glycosylation sequences (Asn–X–Ser/Thr) are underlined.

Fig. 5 Structural features of human factor VIII:C, showing schematically the location of cysteine residues and potential N-glycosylation sites (Asn-X-Ser/Thr) with respect to thrombin cleavage domains. The number of amino acid residues in each domain is given as well as the apparent molecular weights of the corresponding regions of porcine VIII:C.

The location of cysteine residues and potential N-glycosylation sites (Asn-X-Ser/Thr) is shown schematically in Fig. 5. Their exact numerical position within the human factor VIII:C precursor molecule is shown in Fig. 4. The cysteine residues appear to be clustered in the M_r 50,000, 40,000 and 69,000 regions. There are no disulphide bridges between these regions in porcine factor VIII:C, where the same pattern of polypeptides is observed on SDS gels in either reducing or non-reducing conditions.

In contrast to the location of cysteine residues, many of the potential N-glycosylation sites appear between the M_r 40,000 and 69,000 regions (Fig. 5). Distinct bands corresponding to this domain of 908 amino acids, or cleavage fragments derived from it, cannot be readily identified on silver stained SDS gels. We have obtained amino acid sequence data from minor components in purified porcine factor VIII:C preparations which are present in the M_r 80,000 and 50,000 regions of SDS gels. The N-terminal sequences of these polypeptides are identical; furthermore, a similar amino acid sequence is found in the predicted human factor VIII:C precursor amino acid sequence shown in Fig. 4 (residues 760-766).

A striking feature of human factor VIII:C is the presence of repeated blocks of amino acid homology (Fig. 6); the three most extensively repeating patterns of homology are within the M_r 50,000 and 69,000 fragments (blocks A, B, C, D, E and A', B', C', D', E'); within the M_r 50,000 and 40,000 fragments (blocks A, F, G, H, I and A', F', G', H', I') and a M_r 69,000 fragment internal repetition (blocks J, K, L and J', K', L'). Another set of repeat blocks (A', M and A'', M') is suggestive of a vestige of a M_r 40,000/69,000 duplication. Not only is there a strong M to M' homology, but also the A to M spacing is very similar in both regions. A block of amino acids (N) in the 40,000 region is repeated (N') in the region between the M_r 40,000 and 76,000 regions.

We analysed the precursor human factor VIII:C amino acid sequence by the method of Hopp and Woods¹⁹ for the determination of relative hydrophobicity. As observed for other secreted proteins, the factor VIII:C precursor contains a hydrophobic

Fig. 6 Amino acid sequence homology within human factor VIII:C. A computer search for internal amino acid sequence homology was performed using the PEP program in the IntelliGenetics software system. Blocks of homology are labelled alphabetically on the linear maps, with their location and relative size indicated. Matching blocks of homology bear the same alphabetical symbol plus a prime or double prime. The actual amino acid sequences within these blocks and their numerical position with the entire precursor molecule can be located in Fig. 4. A(residues 21-35); A'(400-414); A''(1,714-1,728); B(89-101); B'(1,776-1,788); C(177-198); C'(1,856-1,877); D(211-227); D'(1,902-1,908); E(292-298); E'(1,979-1,985); F(164-179); F'(539-554); G(217-227); G'(594-604); H(250-261); H'(633-644); I(318-324); I'(809-815); J(2,038-2,059); J'(2,191-2,212); K(2,144-2,151); K'(2,301-2,308); L(2,181-2,188); L'(2,338-2,345); M(486-492); M'(1,796-1,802); N(749-755); N'(1,002-1,008).

leader sequence (residues 1-19). Two other extensive regions of hydrophobicity are also predicted by this analysis; first, 27 amino acids from Ser308 to His334 and second, from Ser630 to Phe677. The hydrophobic nature of these regions is substantiated by the method of Kyte and Doolittle²⁰. The role of these hydrophobic regions in factor VIII:C secretion and/or activity is unknown.

Homology with other plasma proteins

We have reported previously²¹ amino acid sequence homologies among certain regions in factor VIII:C, factor V, and ceruloplasmin. These homologies were identified by comparison of the N-terminal amino acid sequences of thrombin cleavage fragments of bovine factor V and porcine factor VIII:C with amino acid sequence deduced from a genomic clone of porcine factor VIII:C and with the published amino acid sequence of human ceruloplasmin²². The deduced amino acid sequence of human factor VIII:C described here (Fig. 4) contains regions of homology with the known amino acid sequences of bovine factor V and extensive homology with the entire human ceruloplasmin molecule, supporting the suggestion that these three proteins are related evolutionarily. Note the homology between blocks A, A' and A'' of human factor VIII:C (Fig. 6) and residues 2-16, 353-366 and 712-726 respectively of human ceruloplasmin²², as these homology blocks apparently mark the boundary of a primordial gene encoding approximately 350 amino acids. Similarly, block A is homologous with residues 3-17 of the M_r 94,000 amino terminal thrombin cleavage fragment of bovine factor V and block A'' is homologous with residues 6-20 of the C-terminal M_r 74,000 thrombin cleavage fragment of factor V²¹. At present, the significance of repeating homologous units in factor VIII:C, factor V and ceruloplasmin is unclear, but they presumably reflect duplications and triplications of some smaller ancestral gene.

We thank Louise Wasley and John Brown for technical assistance; Ed Fritsch and Steve Clark for support and helpful discussions; Joyce Lauer and Katherine Smith for help with the manuscript and Martha Richardson, Marybeth Erker and Cathy Beechinor for word processing. Finally, we thank both Robert Kamen and Gabriel Schmergel for their encouragement throughout the project. This work was supported by Baxter Travenol Inc., the Mayo Foundation and grant HL-17430 to D.N.F.

Cosmic-ray emission from Cygnus X-3

N. A. Porter

Physics Department, University College, Dublin 4, Ireland

Recent observations^{1,2} of the X-ray binary source Cygnus X-3 have revealed a flux of ultra-high energy γ rays. Other observations and subsequent models suggest that Cyg X-3 may be a dominant source of galactic high-energy cosmic rays. Here I investigate whether it is possible to escape this conclusion with a model in which most of the energy of accelerated particles at the source is emitted as curvature radiation (that is, radiation emitted by particles travelling on curved paths in a magnetic field so strong that synchrotron radiation is suppressed). I conclude that such a model is not consistent with the observations.

The ultra-high energy γ -ray flux^{1,2} at 10^{15} – 10^{16} eV from the X-ray binary source Cygnus X-3 has attracted much attention. If the output is in the form of a rotating beam or an interception of a particle beam by a producing medium in the line-of-sight, the estimated³ emission in the energy range is 6×10^{36} erg s⁻¹. The flux at 10^{11} – 10^{13} eV seen by atmospheric Čerenkov groups⁴⁻⁷ also contributes $\sim 10^{37}$ erg s⁻¹, again assuming a beamed emission. This γ -ray component may be significant at high energies in forming cosmic-ray anisotropies⁸. Because of the difficulty in explaining the ultra-high energy flux in terms of electron emission^{2,9,10}, a proton or ion mechanism, probably involving nuclear collisions and production of π^0 -mesons¹¹, seems necessary. Using nuclear interaction models of the source, it has been shown^{12,13} that more than 10^{40} erg s⁻¹ of high-energy cosmic-ray particles are emitted. The calculation of the production and subsequent absorption of γ rays in a uniform medium gives a maximum efficiency of only $\sim 3\%$ for the conversion of a nuclear spectrum into a γ -ray spectrum of comparable exponent. Interstellar absorption, for the accepted distance of 11.4 kpc (ref. 3), raises the observed flux to $\sim 3 \times 10^{37}$ erg s⁻¹ in the region 10^{15} – 10^{16} eV. These are time-averaged fluxes. In a directed effect, in which an isotropic flux of protons or ions strikes an emitting/absorbing medium¹³ and if the observed duty cycle is 0.1 (in ref. 2 it seems to be as low as 0.025), then we arrive at a heavy-particle emission of $\geq 10^{40}$ erg s⁻¹. However, the total cosmic-ray energy injection rate required for the whole Galaxy is thought^{14,15} to be only 10^{40} – 10^{41} erg s⁻¹. Thus a single Cyg X-3 type source could supply the entire cosmic-ray demand up to particle energies of $\sim 10^{16}$ eV.

Hillas¹³ holds that Cyg X-3 can comfortably supply the ultra-high energy galactic cosmic rays in the energy range 10^{15} – 10^{18} eV, but probably does not contribute substantially to the lower energy flux. Does the observed γ -ray flux necessarily imply such large proton fluxes, or are there are mechanisms which could supply the photon component more economically? One possible mechanism, curvature radiation¹⁶, is considered here because it has a very efficient transfer ratio between emitting particles and emitted photons, and because it operates with heavy particles as well as electrons. For the 10^{15} – 10^{16} eV band,

protons or ions are required, but electrons might produce the 10^{11} – 10^{13} eV component. For the 10^{13} – 10^{15} eV interval, for which there is some experimental evidence of emission¹⁷, there could be a combined effect, and indeed the phase of the 4.8-h period emission seems to change between 10^{12} and 10^{15} eV. For either proton or electron emission, however, there is a serious γ -ray absorption problem, arising from pair production in the magnetic field of the pulsar¹⁸. Ignoring this we can calculate, in cgs units, the required power output. For a single particle of unit charge, whether electron or proton, the power output in curvature radiation is:

$$W = 2e^2 c \gamma^4 / 3r^2 \quad (1)$$

With a characteristic γ -ray energy

$$h\nu = 2\pi\hbar c \gamma^3 / r \quad (2)$$

where r is the radius of the orbit, $\gamma = E/mc^2$ for either a proton or an electron, where E is the energy of the proton or electron.

For the 10^{15} -eV γ rays we take $r = 10^8$ cm, for a field line extending from the pulsar pole to the velocity of light cylinder. The frequency $\nu = 10^{30}$ Hz, and from equation (2) we have $\gamma^3 = 3 \times 10^{27}$ or $\gamma = 10^9$. For a proton this gives a particle energy of 10^{18} eV. For orbit radii $< 10^8$ cm, W would be large, resulting in a rapid energy loss, so that the process would not work.

Acceleration to this energy may be electrostatic¹⁰. The field ϵ has a maximum value^{14,15} given by $\epsilon = 10^{-14.2} B r^{3/2} P^{-3/2}$ V cm⁻¹ where B is the magnetic field and P the period; at 10^{12} G and 3 ms respectively we obtain a field of $\sim 2 \times 10^{13}$ V cm⁻¹ near the pole of the pulsar. The distance to the velocity-of-light cylinder is only 10^7 cm, but in the absence of short-circuiting effects, it is not difficult to obtain potentials in the region of 10^{20} eV. An alternative possibility is the mechanism of Gunn and Ostriker¹⁹.

The energy output in curvature radiation from a proton of 10^{18} eV is given by equation (1):

$$W = \frac{2}{3} \times \frac{25 \times 10^{-20} \times 3 \times 10^{10} \times 10^{36}}{10^{16}} \\ = 10^{12} \text{ erg s}^{-1} \text{ or } 30 \text{ erg cm}^{-1}$$

This is essentially equal to the electrostatic energy gained, so that there will be equilibrium between emission and acceleration. For a flight distance 10^7 cm to the velocity-of-light cylinder, we have an emission of 3×10^8 erg at a constant particle energy of 10^{18} eV. To produce 3×10^{37} erg s⁻¹ of γ rays at 10^{15} eV we require 10^{29} particles s⁻¹, each with 10^{18} eV or 10^6 erg, making a total energy flux of $\sim 10^{35}$ erg s⁻¹. We assume that all particles escape on reaching the velocity-of-light cylinder.

Therefore, the proton flux produced might be less by more than two orders of magnitude than the γ -ray flux, and five orders of magnitude less than the 10^{40} erg s⁻¹ required by the nuclear interaction model. A similar calculation for electrons having characteristic energies of 10^{14} eV results in a comparable energy requirement, about 10^{34} erg s⁻¹ of 10^{14} eV electrons producing

$10^{37} \text{ erg s}^{-1}$ of γ rays at 10^{12} eV . The assumptions made about magnetic and electrostatic fields are, of course, optimistic, but a more accurate calculation would probably not differ from the above by more than two orders of magnitude.

There is, however, a severe difficulty in extracting the γ rays from the system without pair production in the magnetic field. There will probably also be considerable but lesser geometrical difficulties in producing the characteristic one or two narrow γ -ray pulses in the 4.8-cycle.

The condition for pair production is $B_{\perp} E_{\gamma} > 10^{18.6}$, with B in gauss and photon energy in electron volts¹⁶. For $E_{\gamma} = 10^{15} \text{ eV}$ the transverse components of B must be $\leq 10^4 \text{ G}$. With a surface field of 10^{12} G and an orbit radius of 10^8 cm this cannot be achieved, and escape would be possible, if at all, only from a position very close to the velocity-of-light cylinder. The difficulties are not quite so severe for 10^{12} eV γ rays. The field at 10^7 cm would be $\leq 10^9 \text{ G}$, and the angle between the photon trajectory and field line could be $< 10^{-2}$, if the orbit radius were increased to 10^9 – 10^{10} cm . This, however, involves increases in electron

energies and fluxes to a point where $\sim 10^{38}$ – $10^{39} \text{ erg s}^{-1}$ are needed to produce $10^{37} \text{ erg s}^{-1}$ of 10^{12} eV γ rays. For protons and 10^{15} eV γ rays it is difficult to see how the model can work without requiring particle fluxes approaching the $10^{40} \text{ erg s}^{-1}$ demanded by the nuclear interaction model.

Another model involves a black hole²⁰. It is not yet clear whether γ rays of 10^{15} eV can be produced in this. Alternatively, emission by quantum synchrotron radiation from electrons in high magnetic fields is possible, but this seems to demand very artificial geometries: electrostatic acceleration of the particles in a region essentially free from magnetic field, followed by almost discontinuous injection into the region of a high field. Otherwise, dissipation of particle energy by low-energy synchrotron emission seems inevitable. Similar models with protons as the radiating particles seem to require unrealistically high particle energies.

The nuclear interaction model needs to be developed to see whether it can produce the experimentally-required spectra and nuclear constitution observed in cosmic rays.

A disk origin for superhumps in Ursae Majoris variables

Keith Horne

Institute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK

As cataclysmic variables, SU Ursae Majoris stars^{1,2} are short-period binary systems consisting of a red dwarf star that fills its Roche-lobe and spills material to an accretion disk around a white dwarf. SU UMa systems undergo outbursts (episodes of increased mass transfer in the disk) of two distinct types: normal outbursts that last a few days, and superoutbursts that last up to 2 weeks. Superhumps are periodic $\sim 30\%$ brightness variations of unknown origin seen only during the superoutbursts. The superhump period is several per cent longer than the binary orbital period. Both the accretion disk^{3,4} and the red dwarf⁵ have been proposed as possible sites for the superhump. Although superhumps occur in both eclipsing and non-eclipsing systems, observations of the eclipsing systems Z Cha and OY Car may help to discriminate between these two classes of models. Whitehurst *et al.*⁶ have shown that the superhumps in Z Cha are not deeply eclipsed, and argue that superhumps therefore cannot originate in the accretion disk. In their starspot model, superhumps arise in a bright active region located in the equatorial belt of the red dwarf. By contrast, the light curve synthesis results reported here show explicitly that disk models produce a shallow partial eclipse of the superhump light, compatible with the eclipse depth measurements of Whitehurst *et al.*, provided the superhump source is not concentrated into a small region of the disk. The starspot model is shown to be inconsistent with the observed shapes of superhumps unless radiation emerges from the starspot in a narrow ($\leq 35^\circ$) fan beam with its long axis in the direction of stellar latitude.

Z Cha is depicted in Fig. 1 as viewed from the Earth at three different orbital phases (ϕ_{orb}). Deep eclipses of the optical light from the system are seen at $\phi_{\text{orb}} = 0.0$ (Fig. 1c), when the red dwarf occults the accretion disk, but secondary eclipses are not seen at $\phi_{\text{orb}} = 0.5$ (Fig. 1a), when the disk occults one hemisphere of the red dwarf. Successive eclipses of the accretion disk occur progressively earlier in the superhump cycle, because the super-

hump period is a few per cent longer than the 107-min orbital period. Eclipse light curves thus probe changes in the structure of the accretion disk during the superhump cycle, and can be used to establish the site of the superhump source.

To determine whether the superhumps in Z Cha are eclipsed, Whitehurst *et al.* measured the brightness of Z Cha at moments of minimum light, when much of the accretion disk is occulted by the red dwarf (Fig. 1c). To correct approximately for secular changes in the brightness of Z Cha during the superoutburst, the fluxes at mid-eclipse are first divided by fluxes at nearby phases that are not affected by either the eclipse or the superhump. Complete coverage of the superhump cycle is achieved by combining measurements from three different superoutbursts. Whitehurst *et al.* found that the normalized mid-eclipse fluxes increased by $\sim 25\%$ for eclipses that occur near the superhump peak, and were roughly consistent at all superhump phases with the expected fluxes for an uneclipsed superhump. Thus the superhump source in Z Cha is not deeply eclipsed.

Fig. 1 Schematic views of the cataclysmic variable star Z Cha, at three different binary phases. The red dwarf star is severely distorted by tidal stresses induced by its white dwarf companion. An accretion disk surrounding the white dwarf is fed gas in a stream from the red dwarf originating at the inner lagrangian point. One hemisphere of the red dwarf is largely eclipsed by the disk (a), and a large area of the disk remains visible at mid-eclipse (c).

Fig. 2 Synthetic light curves for a disk model of superhumps. The upper envelope, giving the superhump light curve in the absence of eclipses, is produced in the model by modulating the surface brightness in the outer annulus of the accretion disk. Eclipses of the disk at different superhump phases are shown. *a*, A complete full annulus at the outer rim of the disk is modulated. The eclipse shapes in this case remain similar throughout the superhump. *b*, The modulation is confined to a single point on the outer rim of the disk. The distorted eclipses found in this case are not observed, ruling out a compact region on the disk as the site of superhumps. In both cases, the mid-eclipse flux is larger during the superhump because the accretion disk is only partially eclipsed.

The absence of deep eclipses of the superhump light in Z Cha does not preclude a disk origin for superhumps. Although the bright central region of the accretion disk is eclipsed, a large fraction of the disk surface remains visible at minimum light (Fig. 1c). A superhump source that is broadly distributed on the face of the accretion disk therefore undergoes a partial eclipse which may be quite shallow, for example, if the superhump light is distributed around the outer annulus of the disk. Thus, the eclipse depth measurements of Whitehurst *et al.* are compatible with partially-eclipsed superhumps produced in the accretion disk. Smak⁶ independently reaches this same conclusion.

The viability of a disk origin for superhumps is explicitly demonstrated by the synthetic eclipse light curves shown in Fig. 2. Here the uneclipsed superhump light curve is the upper envelope of nine individual eclipse light curves, each centred at a different superhump phase. Fluxes at minimum light, marked by stars in Fig. 2, increase during the superhump in the manner required by the eclipse depth measurements of Whitehurst *et al.* The times of minimum light are slightly advanced during the rise of the superhump, and delayed during the decline. Thus the eclipse phase shift discussed by Whitehurst *et al.* in the context of the starspot model is also produced by a disk model.

Fig. 3 The synthetic light curve for a rotating spherical star with a strip of non-uniform brightness around the stellar equator is compared in *a* with an observed superhump light curve of Z Cha. The longitudinal brightness distribution of the fitted model is given in *b*. The light curve peak produced by this starspot model is always broader than the observed superhump, because the light curves of point sources on the stellar equator (undarkened and fully limb-darkened cases are shown) are already too wide. Flux is given in arbitrary units.

The qualitative behaviour illustrated by this simulation of superhumps from the accretion disk is not sensitive to errors in the assumed geometry of the Z Cha system, to specific details of the accretion disk model, or to the assumed spatial distribution and temporal development of the superhump light, provided only that the superhump source is broadly distributed on the accretion disk. The eclipse geometry (Fig. 1) is the same as that assumed by Whitehurst *et al.* The accretion disk brightness distribution is a steady-state black-body accretion disk model that roughly reproduces the shape and depth of the observed eclipses of Z Cha during superoutburst. The red dwarf is assumed to contribute no light.

The uneclipsed shape of the superhump can be specified arbitrarily and is therefore not an important feature of the simulation. The superhumps in Fig. 2 are produced by modulating the temperature (T) of the outer annulus of the accretion disk according to $T \propto \exp(-2 \cos \phi_{sh})$, where ϕ_{sh} is the superhump phase. This specific form is motivated by the model of Papaloizou and Pringle³ in which mass transfer from the red dwarf varies exponentially with small changes in the binary separation caused by a slightly eccentric orbit, while the discrepant orbital and superhump periods are explained as a precession of the line of apsides.

If the superhump light curve in the absence of eclipses is known, the observed eclipse light curves give detailed information about the spatial distribution of the superhump source on the accretion disk. The eclipse shapes are not strongly affected

Fig. 4 The starspot model fails to produce the sharply-peaked superhumps observed in OY Car. Two models with different longitude resolution are shown. *a* and *b* are as in Fig. 3.

by the superhump if, as in Fig. 2*a*, the superhump light is uniformly distributed around the outer annulus of the disk. A superhump source confined to a compact region on the accretion disk produces highly distorted eclipses (Fig. 2*b*). Because such distortions are not observed, the main source of superhump light cannot be the white dwarf, the compact hotspot where the gas stream from the red dwarf feeds matter to the accretion disk, or any other compact region on the accretion disk. More detailed modelling of the eclipse observations will refine our knowledge of the spatial distribution of the superhump source, but this programme is complicated by the need to disentangle changes in the eclipse shapes from changes in the shape of the superhump. The slow march of the eclipses across the superhump light curve occurs on a time scale comparable with that for secular evolution of the superhump light curve itself.

In the starspot model proposed by Whitehurst *et al.*, superhumps are caused by a bright active region on the red dwarf. The discrepancy between the orbital and superhump periods is interpreted as a slight prograde rotation of the red dwarf in the frame of the orbital motion of the binary. The bright starspot must lie near the stellar equator to avoid occultation at $\phi_{\text{orb}} = 0.5$ by the accretion disk, because secondary eclipses are not observed.

Synthetic light curves for the starspot model are compared in Figs 3 and 4 with the observed superhump light curves of OY Car and Z Cha. Observations of OY Car by Kzreminski⁷ are shown in Fig. 3*a*. Warner's observations of Z Cha, as given by Cook⁸, are shown in Fig. 4*a* (also Fig. 2 of Whitehurst *et al.*). The light curves show typical examples of the large superhumps that develop a few days after the start of a superoutburst. A constant, equal to the depth of the eclipse, is subtracted from the original data to remove the light of the accretion disk. The amplitude of the brightness variation to be accounted for by the rotating

spotted star is thereby underestimated, as part of the light visible at mid-eclipse is, in fact, from the accretion disk. The accretion disk eclipses, which occurred at $\phi_{\text{sh}} \approx 0.5$ for Z Cha and $\phi_{\text{sh}} \approx 0.6$ for OY Car, are removed by interpolating observations before and after the eclipse.

Light curves for the starspot model are computed by summing contributions from an array of discrete sources distributed over the surface of the rotating star. The flux contributed by each visible source is given by $f = f_0 \cos \theta [1 - B + B \cos \theta]$, where θ is the angle between the line-of-sight and the normal to the stellar surface, f_0 is the flux when viewed normally, and B is the limb darkening parameter. The first $\cos \theta$ factor accounts for foreshortening, while the term in brackets approximates limb darkening for normal stellar atmospheres. The synthetic light curves shown in Figs 3*a* and 4*a* are for a ring of 100 fully darkened ($B = 1$) sources equally spaced around the equator of a spherical star.

The fluxes f_0 are constrained to be positive but otherwise are free to vary in fitting the observed light curve. Equatorial brightness distributions corresponding to the light curve fits in Figs 3*a* and 4*a* are given in Figs 3*b* and 4*b*. In the effort to produce a sharp peak corresponding to the superhump, the stellar brightness distribution breaks up into five precisely arranged bright regions. The structure in the synthetic light curves around $\phi_{\text{sh}} = 0.5$ is also an artefact of this failed attempt to produce a sharp peak. Calculations with sources covering the full stellar surface, with limb darkening parameters in the range $0 < B < 1$, using the correct Roche geometry, and including the eclipse of the red dwarf by the accretion disk, give similar results.

All of the starspot models considered here fail to produce light curves as sharply peaked as the observed superhumps. The starspot models fail because the light curve for a point source on the stellar equator, shown in Fig. 3*a* for undarkened ($B = 0$) and fully darkened ($B = 1$) cases, is already broader than the observed superhump. Any extended brightness distribution must produce an even broader peak. A bright spot at high stellar latitude produces a narrower peak by being visible for less than half of the rotation period, but such spots are ruled out by the absence of secondary eclipses.

The starspot model is thus incompatible with the observed superhump light curves, unless radiation from the starspot is beamed to a considerably greater extent than the radiation from a normal stellar atmosphere. The sharply peaked superhump light curves require the starspot radiation to emerge with an angular full width at half intensity of about 35° , compared with 90° – 120° for limb-darkened stellar atmospheres. As superhumps are seen in both eclipsing and non-eclipsing systems, this beaming must apply only to the direction of stellar longitude. Thus if superhumps arise on the red dwarf, some mechanism must be found to confine the radiation from the bright starspot to a narrow fan beam with its long axis in the direction of stellar latitude.

Light curve synthesis techniques have been used here to clarify the direct constraints that are placed by the light curves of eclipsing SU UMa systems on possible sites for superhumps. These constraints apply without regard to the physical mechanism responsible for superhumps, because they depend only on the well-understood geometry of eclipses in a binary system. Superhump sites at high stellar latitude on the red dwarf are eliminated by the absence of secondary eclipses at $\phi_{\text{orb}} = 0.5$. Sites near the stellar equator are feasible only by invoking a narrow fan beam radiation pattern to explain the sharply pointed shapes of superhumps together with the occurrence of superhumps in both eclipsing and non-eclipsing systems. The shapes of superhumps do not directly constrain disk models, in which the superhumps are produced by time variation rather than by occultation of the superhump source. The absence of deep eclipses of the superhump light in Z Cha, and the shapes of eclipses that occur during the superhump peak independently rule out compact sources on the accretion disk. There is no apparent conflict between the extant eclipse observations and a superhump source that is broadly distributed over the face of

the accretion disk. A more delicate analysis of the eclipse light curves should sharpen the observational constraints on the distribution of superhump light on the face of the accretion disk.

I thank G. Bath, B. Warner and J. Pringle for useful discussions.

Differentiation between ^{27}Al nuclei in alums by Fourier transform pure nuclear quadrupole resonance

D. B. Zax, A. Bielecki & A. Pines

Aluminium is the most abundant metal in the Earth's lithosphere and is present in many commercially important materials. Recent studies on its role in zeolites¹ and proposed solar energy storage schemes involving aluminium salts² have led to renewed interest in analytical methods capable of identifying and characterizing specific crystalline sites. In particular, new techniques are necessary which do not require single crystals. One such technique is Fourier transform nuclear quadrupole resonance (NQR) with pulsed field cycling^{3,4}, and we report here on its application to the determination of specific ^{27}Al sites in model aluminium compounds, the alums.

In crystalline compounds, aluminium occurs most often with either four or six nearest neighbours. Tetrahedrally coordinated aluminium is the catalytically active centre in zeolites, where each ^{27}Al atom is believed to be surrounded by four O-Si linkages. The octahedral form, as characteristically found in the alum family, surrounds each ^{27}Al site by six bonds (often to H_2O molecules). Much work has gone into characterizing these sites. In powder samples, the NMR spectra are very broad and the methods used to obtain information have been two-dimensional solid state NMR⁵ and magic angle sample spinning (MASS) NMR⁶. Although the latter technique has proved useful in studies of ^{29}Si in zeolites^{7,8}, its applicability to aluminium is limited because of the small dispersion in ^{27}Al chemical shifts and the line broadening arising from quadrupolar effects, with the result that it generally reveals only the difference between tetrahedral or octahedral sites^{9,10}, except in rare cases of resolution between tetrahedral sites¹¹. As an example, Fig. 1 shows MASS spectra of ^{27}Al in two closely related materials, the ammonium and potassium alums ($\text{NH}_4\text{Al}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$ and $\text{KAl}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$). This technique reveals no difference between these two samples.

In contrast to high field NMR techniques, magnetic resonance should readily differentiate between signals from similar sites in a zero applied magnetic field; we rely in this instance on the inherent chemical sensitivity of the nuclear quadrupole interaction to resolve structural differences. The quadrupolar interaction arises from the coupling of a non-spherical nuclear charge distribution (characteristic of any nucleus where I , the nuclear angular momentum operator, is less than $\frac{1}{2}$) to molecular and crystalline electric field gradients. In ^{27}Al sites of high symmetry,

Fig. 1 ^{27}Al magic angle spinning spectra of representative alums. Spectra are observed at 78.2 MHz at a spinning rate of 4 kHz. Chemical shifts are referenced to $\text{Al}(\text{H}_2\text{O})_6^{3+}$. The mixed alum sample is 56 mol% potassium alum, 44 mol% ammonium alum.

Fig. 2 Schematic diagram showing the effective field at the sample as a function of time. The sample is pneumatically transported from the bore of superconducting magnet B_0 to a point where B_1 accurately compensates for the fringe field. Coil B_2 (0.03 T) is switched off for a time t_1 during which pure quadrupolar evolution occurs. After returning the sample to B_0 , the high field magnetization, $S(t_1)$, is measured. The cycle is repeated for equally spaced points in t_1 until no further change in magnetization is observed. Fourier transformation of the magnetization as a function of t_1 results in the zero field spectrum.

the magnitude of the field gradient term is small. Direct detection of the pure NQR transitions is thus difficult (as the energy splittings are small¹²).

We instead used the chemical sensitivity of pure NQR, in combination with the high signal-to-noise ratio associated with observation of NMR in large applied magnetic fields. This is done by cycling the magnetic field between a large value and zero, and is accomplished in two steps (see Fig. 2): first, the sample is mechanically transported from the bore of a superconducting magnet and then the residual field is pulsed to zero with electronically switched coils. If the second stage occurs quickly relative to the quadrupolar frequencies, the spin system in zero field oscillates at frequencies characteristic of the pure quadrupolar coupling. This oscillation is interrupted at time t_1 by reapplying the field. The sample is then returned to high field where the signal amplitude is monitored. This field cycle is

Fig. 3 ^{27}Al Fourier transform pure nuclear quadrupole resonance spectra of representative alums. Each site contributes two lines to the zero field spectrum. η , asymmetry parameter in the quadrupole tensor, was calculated to be 0.17 for potassium alum and ammonium alum. Respective values of 391 and 438 kHz were obtained for the quadrupole coupling constant, $(e^2qQ)/h$, where eQ is the nuclear quadrupole moment, eq is the electric field gradient, and h is Planck's constant. The pair of high frequency lines in the mixed sample (56 mol% potassium alum, 44 mol% ammonium alum) clearly indicate the existence of two distinct ^{27}Al sites.

repeated with different, equally spaced values of t_1 , to give an interferogram which describes the evolution of the spin system in zero field and which, on Fourier transformation, yields the zero field spectrum.

For a spin- $\frac{5}{2}$ nucleus such as ^{27}Al , we expect to observe a pair of lines for each crystalline site. (In aluminium compounds where the crystal symmetry is low, a third line of low intensity may be observed.) Figure 3 illustrates the results for the two alums whose MASS spectra are shown in Fig. 1. Despite nearly identical crystal structures and high field NMR spectra, the zero field nuclear quadrupole experiment clearly differentiates between the two types of aluminium nuclei. We expect that even more sensitive differentiation will be possible between ^{27}Al sites in other systems such as zeolites.

Direct determination of strontium enrichment on grain boundaries in a garnet lherzolite xenolith by proton microprobe analysis

Donald G. Fraser*, F. Watt†, G. W. Grime† & J. Takacs†

* Department of Earth Sciences, University of Oxford, Parks Road, Oxford OX1 3PR, UK

† Department of Nuclear Physics, University of Oxford, Keble Road, Oxford, OX1 3RH, UK

The mechanisms by which trace and radiogenic elements are held and transported in the Earth's mantle are of prime importance in studies of basalt petrogenesis and the chemical processing of the mantle. While such mechanisms include the migration of melts and the convective physical admixture of differentiated material¹, the role of fluids as transport agents has attracted much interest, especially, in regions affected by kimberlitic activity^{2,4}, continental basaltic volcanism^{5,6}, and in areas of subduction-related magmatic activity^{7,8}. The observation that many incompatible elements are readily leached from garnet lherzolites by dilute acid treatment³ has led to the assumption that a proportion of these elements is located on grain boundaries, rather than in solution in the various minerals present. This indirect evidence is reinforced by comparison of the compositions of mineral separates with their bulk parental material^{4-8,11}. Although careful electron microprobe analyses have made it possible to detect minor and trace elements within grains¹², the low concentrations involved, together with the high X-ray background of the electron microprobe, have made it impossible to investigate the supposed distribution of incompatible trace elements on grain boundaries. We have measured directly, using a high-resolution proton microprobe^{9,10}, the distribution of Sr and other elements in a garnet lherzolite xenolith. The analyses demonstrate that, in this sample, Sr is preferentially concentrated along grain boundaries.

An inherent limitation in the use of the electron microprobe to analyse very small concentrations of elements lies in the substantial non-characteristic X-ray background caused by electron *bremsstrahlung*. This is very much reduced when a proton beam is used to excite X rays in a sample because the enormously increased mass of the proton minimizes the amount of deceleration near the target. In the present experiments, the specimens were analysed by using a 4.0-MeV proton beam to excite characteristic X rays in the samples. The beam was focused electromagnetically to a spot diameter of 2 μm and was rastered over an area of up to 4 mm $\times$ 4 mm. The samples were prepared as 30- μm thin sections and the X rays generated were detected and analysed using a Link Si(Li) detector system. As the penetration of a proton beam is much greater than that of a beam of electrons in an electron microprobe, the sections were mounted on glass slides using Lakeside 70 thermoplastic resin as a mounting medium. The sections were then removed from the glass slides by gentle heating and remounted over 1-cm holes machined in aluminium target holders to remove any possibility of X-ray generation in the specimen backing. The resulting targets were finally washed carefully in acetone to remove any traces of resin. Samples were irradiated for ~ 10 h using a 50 μm Al filter to cut out the low-energy X-ray background, and maps of the distribution of X rays from major and trace elements in the samples were built up as 256 $\times$ 256 pixel images. As the proton beam penetrated right through the thin samples used, the transmitted beam current was also continuously measured for each pixel so that the effects of any fluctuations in beam current could be corrected. A detailed description of the Oxford proton microprobe system is given elsewhere^{9,10}.

Figure 1 shows elemental maps for the distribution of Ni, Mn, Cr and Sr in a 4 mm $\times$ 4 mm area of a granular garnet

Fig. 1 Elemental X-rays maps of the distribution of Ni (a), Cr (b), Mn (c) and Sr (d) in a 4×4 mm thin section of a coarse garnet lherzolite xenolith obtained using the proton microprobe. Ni, Cr and Mn are present within the mineral grains, but Sr is concentrated on the grain boundaries. Dark areas indicate high concentrations of the elements.

lherzolite xenolith (MK 15) collected from the Bultfontein dumps. The images were displayed in false colour according to the number of X-ray counts per pixel, but are reproduced here as black and white photographs in which the dark areas represent the highest concentrations. The section consists of an angled grain of orthopyroxene (Cr- and slightly Mn-rich and Ni-poor) surrounded by Ni-rich olivine, and there is no obvious zoning in the concentrations of these elements. In marked contrast to the distribution of Cr, Mn and Ni, the map of Sr distribution shows almost no Sr in the interiors of the grains; instead, Sr is concentrated along grain boundaries in the specimen. The Sr was clearly introduced into the rock after its present texture had formed and comparison with the thin section shows that it is located on the serpentinized grain boundaries and cracks in the mineral grains.

To provide an estimate of the concentration of Sr represented in Fig. 1, the data were calibrated by analysing samples of clinopyroxenes which had been analysed previously as mineral separates by isotope dilution¹³. The standards were also prepared as 30- μ m thin sections and data were collected from each standard as the number of Sr-K α counts per nanocoulomb of beam charge deposited on the target. A plot of the count rates against the Sr-contents of the three clinopyroxenes used as standards is given in Fig. 2. The Sr concentrations along the grain boundaries of the garnet lherzolite xenolith, shown in Fig. 1, produced 6–36 counts per nanocoulomb per pixel corresponding therefore to a range of 100–600 p.p.m.

Fig. 2 Calibration of Sr count rates. The number of counts per nanocoulomb of deposited proton charge is plotted against the Sr concentrations of clinopyroxenes which had been analysed for Sr by isotope dilution.

Fig. 3 Elemental X-ray maps of the distribution of Ni (a), Cr (b) and Sr (c) in a thin section of a mosaic porphyroclastic garnet lherzolite xenolith. In this specimen, Sr is distributed like the other trace elements within mineral grains and there is no sign of the process which caused the concentration of Sr on grain boundaries in the specimen in Fig. 1.

Although it is highly unlikely that Sr at these levels could have been introduced into the sample during preparation of a thin section, a second garnet lherzolite sample was selected and prepared in the same way for analysis. This sample (BD 2501) had a mosaic porphyroclastic texture¹⁴, and was known, on the basis of previous studies¹³, to be, of all the xenoliths, one of the least affected by acid leaching. Elemental maps were built up as before and the images for Sr, Ni and Cr in a 4 mm×4 mm section are shown in Fig. 3. The area analysed contains clinopyroxene and garnet grains at the top and bottom of the photographs respectively, separated by a larger Ni-rich olivine grain. The results are in marked contrast to the data shown in Fig. 1 and indicate that, in this sample, there is no detectable concentration of Sr on grain boundaries. Instead, the Sr is present within the mineral grains, the majority being in the clinopyroxene, but with detectable levels in the garnet also. The absence of Sr located along grain boundaries in this section, therefore, makes it unlikely that the data shown in Fig. 1 are an artefact of sample preparation.

These preliminary results provide direct evidence for the location of Sr on serpentinized grain boundaries in certain samples from the upper mantle and strongly suggest the role of an aqueous fluid as the transporting agent. They also indicate the success of the high-resolution proton microprobe as an instrument for determining the concentrations and spatial distribution of trace elements in geological samples. Detailed isotopic work on the timing and nature of the event responsible for the introduction of Sr into the xenolith shown in Fig. 1 will be presented elsewhere (D.G.F. and S. Beswetherick, in preparation).

D.G.F. acknowledges financial support from the NERC and the Anglo-American Corporation. We thank Dr S. Beswetherick for providing the analysed specimens used as calibration points.

Upwarp of anomalous asthenosphere beneath the Rio Grande rift

Continental rifts are possible analogues of mid-ocean ridges, although major plate tectonic features are less clearly observed¹. Current thermal models of mid-ocean ridges²⁻⁴ consist of solid lithospheric plates overlying the hotter, less viscous asthenosphere, with plate thickness increasing away from the ridge axis. The lithospheric lower boundary lies at or near the melting point isotherm, so that at greater depths higher temperatures account for lower viscosity, lower seismic velocities and possibly partial melting. Upwarp of this boundary at the ridge axis concentrates heat there, thus lowering densities by expansion and raising the sea floor to the level of thermal isostatic equilibrium. At slow spreading ridges, a major central graben forms owing to the mechanics of magma injection into the crust⁵. Topography, heat flow, gravity and seismic studies support these models. On the continents, a low-velocity channel has been observed, although it is poorly developed beneath ancient cratons⁶⁻⁹. Plate tectonic models have been applied to continental basins and margins¹⁰⁻¹², but further similarities to the oceanic models remain elusive. Topographic uplift is often ascribed to Airy type isostatic compensation caused by crustal thickening, rather than thermal compensation in the asthenosphere. Here we discuss the Rio Grande rift, in southwestern United States. Teleseismic P-wave residuals show that regional uplift is explained by asthenosphere uplift rather than crustal thickening.

The Rio Grande rift extends for at least 950 km from central Colorado through New Mexico into Mexico. It separates the Great Plains to the east from the Colorado plateau and basin

Fig. 1 *a*, East-west Bouguer gravity profile across the United States at latitude 37° N. The Valles caldera and Rio Grande rift lie within the most negative trough. *b*, Three-dimensional perspective view of Bouguer gravity showing locations of teleseismic stations, and Rio Grande River (---). *c*, Three-dimensional perspective of topography showing regional uplift, which is inversely correlated to the gravity of *b*.

and range province to the west and lies just east of the continental divide¹³. Figure 1 shows the transcontinental Bouguer anomaly at 37° N latitude, which crosses the rift along the New Mexico-Colorado border. The rift lies in a region containing the most negative Bouguer anomalies in the continental United States. Figure 1*b* and *c* are three-dimensional perspectives of the regional gravity and topography, which at long wavelengths are inversely correlated. Our experiment investigates whether the basis of the correlation is crustal or asthenospheric.

Rayleigh wave depths to the continental low-velocity zone of the asthenosphere range from about 70 km (refs 8, 9) in the Great Basin of Nevada and western Utah to 83-145 km (ref. 7) in the south-central part of the continent. Although the gravity and topography variations of Fig. 1*b, c* have been attributed^{14,15} to such undulation of lithospheric thickness, the boundary shape has not been determined directly. To probe the Earth to this depth, a high-energy seismic source is required. This is most conveniently supplied by distant earthquakes in the form of teleseismic waves.

The teleseismic P-wave technique¹⁶⁻¹⁹ consists of timing arrivals from distant earthquakes and subtracting from them tabulated²⁰ arrival times for a laterally homogeneous Earth. Any residuals remaining are attributed to lateral heterogeneity

beneath the seismic array, because distant heterogeneities, such as those at the source, will be attenuated by geometric spreading. Incidence and azimuthal angles are calculated from source parameters using a standard Earth model. The pattern of residuals has been observed to shift in response to different incidence and azimuthal angles in the incoming waves. Given enough rays at different angles, the data can be inverted to determine velocity at depths of up to about half the array dimension, with a resolution equal to station spacing near the surface but decreasing with depth.

Figure 2 shows the locations of the 20 recording stations along the 1,000-km line used for the 1982–83 experiment. A north-west–south-east orientation was taken because teleseismic arrivals lie predominantly along this azimuth so that rays from the north-west and south-east intersect in regions lying beneath the array. The array ran from late November 1982 until late January 1983.

Of the 60 earthquakes recorded, 40 have sufficient signal-to-noise ratio to be used in an inversion. Twenty-five of these lie along the array azimuth. The relative P-wave arrival times can be measured to 0.1 s. Residuals are found by subtracting travel times, obtained from the Herrin²⁰ tables, from the arrival times. Relative residuals, formed for each event by subtracting the mean from the raw residuals, are plotted in Fig. 3a. Some of the scatter is due to changes of the residual pattern with the incidence and azimuthal angle.

Additional assumptions must be made if we are to find an unequivocal interpretation for the residual pattern. Therefore, we assume that the regional shifting pattern is mainly due to upwarp of the asthenosphere–lithosphere boundary, that localized heterogeneity gives rise to the small-scale variations, and that the boundary in the vicinity of our array is approximately two-dimensional with a north–south strike. We used synthetic models to test for a way of inverting for such a boundary and decided on two methods: (1) downward projection of the data to give the boundary shape directly²¹ and (2) the two-dimensional^{19,22,23} damped, least-squares block method to give the averaged velocity distribution. Both methods gave similar results (Fig. 3b, c).

The projection method assumes that the interface is not too deep and that velocity contrasts are not too extreme, so that a straight ray and plane wave approximation for the teleseismic waves is adequate. The arrival time residuals will then be proportional to the length of the ray in the anomalous velocity zone, with the proportionality dependent on the velocity contrast. The raw residual pattern gives a distorted picture of the interface—it is projected onto a rotated axis—but as we know the angle of incidence, we can transform the projection to regain the original shape. The transformed patterns are then projected down each ray and the position of maximum overlap determines the true depth. Maximum overlap was determined by minimizing the sum of squares of residuals to a sixth-order polynomial fit by varying both depth and velocity contrast. Figure 3b shows the best-fit model which has a depth range of 70–200 km and a P-wave velocity contrast of –8% relative to a value of 8 km s^{–1} above the boundary. The average misfit of the polynomial to the data was 0.3 s.

The block model involves dividing the region into two-dimensional blocks and determining the velocity perturbations that give the observed delays. After running a series of tests to determine the uniqueness and minimum parameterization of the block model and having found an optimal model, we tested the hypothesis that all the residuals are due to slowness located in the crust or upper lithosphere rather than at depth. The hypothesis was rejected at the 99.9% confidence level: the data require a deep low-velocity zone. Thus, the model we present (Fig. 3c) has interfaces at 40, 70 and 200 km. A block width of 100 km was chosen because our station spacing ranged from 30 to 140 km. The main feature of this model is a spatially coherent 500-km broad, low-velocity zone of –0.35% to –5.1% contrast, in the depth range 70–200 km. Smaller variations in the upper two layers are incoherent. Incoherency was also found

Fig. 2 Station locations. Each consists of a 1-Hz, L4C vertical seismometer and recorder.

Fig. 3 a, Teleseismic P-wave residuals (de-measured) for 22 events. b, Downward projection of the residual patterns (of a) along ray paths, after rotation to correct for incidence effects. An approximate shape of the inferred lithosphere–asthenosphere boundary is given by the sixth-order polynomial fit. c, Block and polynomial model comparison. Numbers refer to per cent velocity changes compared with –8% contrast found for the polynomial model. Layer interfaces were taken at 40, 70 and 200 km, with unperturbed layer velocities of 6.5, 8.0 and 8.0 km s^{–1}, respectively. d, Gravity anomaly measured along the teleseismic array compared with gravity calculated from the polynomial model of b.

in an additional layer, 130 km thick, when added to the base of the model. The negative anomaly remained unaffected. Standard errors given by the least-squares solution are all $\sim 0.6\%$. The diagonal elements of the resolution matrix ranged from 0.55 in the top layer to 0.86 in the lowest layer. Average misfit for the final model is 0.297 s.

The Bouguer gravity anomaly calculated for both the polynomial model and the block model shows good agreement with the measured data for the area. Figure 3d shows the fit for the gravity values calculated from the polynomial model for which the adjusted density contrast in the low-velocity zone gave a value of -0.05 g cm^{-3} , that is, $\sim 1.6\%$ of 3.2 g cm^{-3} . The ratio of velocity to density contrast, 5.0, is much larger than expected from the Nafe-Drake²⁴ relationship determined from different types of igneous rock, which gives a value of ~ 0.8 . Such an increase in the sensitivity of velocity to change in density is consistent with the presence of a small fraction of partial melt within the low-velocity zone which, while having little effect on density, will have a disproportionately larger effect on shear modulus and hence P-wave velocity. High attenuation supports this view. P-wave amplitudes measured at Albuquerque, which lies on the rift, are among the most attenuated of those measured at standard stations in the United States²⁵. Greater attenuation is seen only at Golden, Colorado, to the north, on the Rocky Mountain front.

The topography also agrees qualitatively with that in isostatic balance with the polynomial model, that is, in thermal isostatic equilibrium. Therefore, the model we assume to explain the teleseismic delays, attenuation²⁵, gravity, uplift^{14,15}, regional heat flow²⁶ and the presence of rifting and volcanism, is based on a hot, low-density asthenospheric body which has replaced the lithosphere by upward movement of the lithosphere-asthenosphere boundary. Such migration of the melting point geotherm might be caused by either lithospheric extension¹⁰ or active convection²⁷ in the upper mantle and requires further quantitative work to elucidate the mechanism. Nonetheless, the boundary has a configuration expected to exist in a region as a prelude to the opening of oceans and continental drift. Although the polynomial fit of Fig. 3b shows some agreement with lithospheric depths determined from Rayleigh waves, other points are still unresolved. Where low P-wave velocities have been associated with low S-wave velocities^{9,28,29} in the low-velocity zone, the per cent reduction in P-velocity is about half that in S-velocity. Our model reduction in P-velocity is -8% , implying an unprecedented regional reduction of S-velocity of -14% . Also, the low-velocity zone has been associated with increased density values^{7,28}, which is opposite to our conclusion. If we compromise between less P-wave velocity perturbation and increased amplitude of the variation of the boundary, the flanks would be placed too deep for them to interface with surface wave models of lithospheric thickness. Therefore, if asthenospheric upwarp is to explain the gravity, topography and teleseismic delays, the properties of the asthenosphere in this region must differ from those encountered elsewhere. However, we might expect this, as it underlies the most negative region of the east-west, continental Bouguer gravity profile (latitude 37° , Fig. 1).

Enhanced preservation of marine-derived organic matter in Cenomanian black shales from the southern Angola Basin

P. A. Meyers*, M. J. Leenheer†, O. E. Kawka*‡

Tulsa Oklahoma 74102, USA

Black shales possessing high concentrations of organic carbon¹ were deposited in many parts of the proto South Atlantic Ocean during the Cretaceous period². The way such sediments accumulated is not fully understood, but is likely to have occurred through a combination of low oxygen availability and abundant supply of organic matter. Thin, centimetre-thick layers of black shales are commonly interbedded with thicker layers of organic carbon-deficient, green claystones, as found in strata of Aptian to Coniacian age, at Deep Sea Drilling Project (DSDP) Site 530, in the southern Angola Basin³ and elsewhere. These differences in carbon content and colour reflect the conditions of deposition, and possibly variations in the supply of organic matter^{4,5}. We have compared, using organic geochemical methods the compositions of organic matter in three pairs of closely-bedded black and green Cenomanian claystones obtained from Site 530. Kerogen analyses and distributions of biological markers show that the organic matter of the black shales is more marine and better preserved than that of the green claystones.

The results of the analyses are presented in Table 1. X-ray diffraction studies do not show any significant differences between the mineralogical contents of the black and green claystones. Furthermore, the pyrite content of adjacent intervals is similar: its relative abundance seems to depend more on the depositional setting than on the amount of organic matter in the sediments.

Values of total organic carbon, however are significantly higher for the black shales than for their green claystone pairs. Modern deep-sea sediments generally contain $\sim 0.2\%$ organic carbon⁶. Values as high as in these black shales are found in only a few areas of present-day oceans⁷, which are under anoxic or poorly oxygenated bottom-waters. A rare combination of abundant supply and exceptionally good preservation of organic matter is needed for such organic carbon-rich sediments to accumulate.

Visual kerogen analysis of the green and black claystones shows that both contain two populations of vitrinite and amorphous kerogen. Whereas the indigenous vitrinite content indicates that the samples are thermally immature, Fig. 1 shows that the green claystones differ from the black shales in containing a larger amount of recycled vitrinite having a higher thermal

‡ Present addresses: School of Oceanography, Oregon State University Corvallis, Oregon 97301, USA (O.E.K.); Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA (T.W.T.).

Fig. 1 Vitritine reflectance histograms of composite samples of Cenomanian black shale (*a*, mean = 0.545, median = 0.535, s.d. = 0.195, count = 37) and green claystone (*b*, mean = 0.457, median = 0.450, s.d. = 0.113, count = 35) from DSDP Site 530 in the Angola Basin. Hatched area represents indigenous population.

maturity. Similarly, populations of spores present in the green claystones range from transparent to dark orange, indicating a wide range of thermal maturities, whereas the black claystones contain primarily light-coloured, thermally immature spores. Also the amorphous kerogen of the green claystone is ~85% fluorescent compared with 100% in the black shales. Because thermally immature amorphous kerogen is highly fluorescent, the lower percentages in the green claystones suggest they contain a significant amount of nonfluorescing detrital material. The presence of two populations of both vitritine and amorphous kerogen, indicated as in Fig. 1 by the vitritine reflectance histograms, and by visual inspection, implies there are differences in the organic matter intake and preservation of the two claystones.

The mean value of organic matter C/N atomic ratios is much greater for the black shales (38.1) than for the green claystones (5.7) and is typical of C/N ratios of cellulosic land-plant organic matter⁸. The ^{13}C content of organic matter in black shales from Site 530 is generally less than in green claystones. This difference in isotopic compositions could mean there is a larger component of land-derived organic material in the black than in the green strata. Characterization of organic matter by kerogen analysis, however, shows that the black shales of the Angola Basin contain more amorphous kerogen, indicative of their aquatic origin, than do the green claystones¹⁰⁻¹².

Fig. 2 Gas chromatograms showing extractable aliphatic hydrocarbon distributions of adjacent samples of black (*a*) and green (*b*) claystones from Hole 530A. Pristane and phytane are identified as PR and PH, respectively, and *n*-alkanes by their carbon numbers.

The contradictions in the identification of the source of organic matter, apparent between the C/N ratios and carbon isotope content and the kerogen analyses may arise from selective preservation of organic matter components. Although preservation is generally high in the black shales, nitrogenous materials appear to have been selectively lost, thus enhancing C/N ratios. Similarly, classes of organic compounds relatively rich in ^{13}C , such as amino acids and carbohydrates, may have been selectively degraded, as reported in sediments from Mangrove Lake³, resulting in reduced ^{13}C in the residual organic matter of the black shales. Poorer preservation in the green claystones has led to losses of all but the most resistant forms of organic matter.

Geolipid data agree with this picture of selective preservation. Concentrations of total hydrocarbons, fatty acids, and fatty alcohols are significantly greater in the black shales than in the adjacent claystone (Table 1), yet these geolipids often constitute a smaller fraction of the total organic matter in black shales than in green claystones¹⁴, which is consistent with greater preservation of the more degradable, non-lipid organic matter components in the black shales.

The hydrocarbons in the samples are a combination of compounds either introduced as such to the sediments or generated during diagenesis. The large amounts of aliphatic and aromatic hydrocarbons, in contrast to the smaller amounts of alkanols

Aromatic hydrocarbons (p.p.m.)	6	695	20	202	284	126
Alkanoic acids (p.p.m.)	3	7	2	6	11	3
Alkanols (p.p.m.)	0.4	5	2	5	9	3

Samples for geochemical comparison, taken from ~1,020 m sub-bottom depth, were selected onboard ship and immediately frozen to protect their organic matter. Analysis of organic carbon and of solvent-extractable geolipids were done as described elsewhere¹⁴. Kerogen was isolated by demineralization and flotation, and analysed microscopically in both transmitted and reflected light. Bulk mineralogy was determined by X-ray diffraction.

Fig. 3 GC-MS mass fragmentograms of steranes, triterpanes, and diterpanes extracted from black and green claystones from DSDP Hole 530A. The labelled steranes possess unaltered biological 5- α (H), 20- R configurations. The C₂₉ to C₃₁ triterpanes have 17- α (H), 21- β (H) configurations unless labelled as BB. Hopanes are indicated by *, and moretanes (17- β (H), 21- α (H) configurations) by M.

and alkanolic acids in all samples, suggest that a significant amount of these components were generated after deposition and, hence, may reflect diagenetic processes rather than selective preservation as suggested for the more labile compounds. Whereas both types of sample have relatively large amounts of long chain ($>C_{25}$) *n*-alkanes with a pronounced odd-carbon preference, suggesting terrigenous input, Fig. 2 shows that the black claystones also contain significant amounts of shorter chain *n*-alkanes and branched and cyclic hydrocarbons, which are not present in the green claystones^{14,15}. These aliphatic hydrocarbons and the larger quantities of C_{27} relative to C_{29} sterane, which are more evident in the black than in the green claystones (Fig. 3), suggest somewhat more aquatic input to the black claystone. In addition, the presence of diterpanes, predominantly C_{19} and C_{20} , in the green claystone, which are absent from the black claystone (Fig. 3) suggests the input of mostly terrigenous, microbially-altered material to the green claystone^{16,17}. The unidentified peaks in the *m/z* 191 trace of the black claystone probably represent tetracyclic terpanes of unknown origin. Hence, the hydrocarbon analysis agrees with the character of the organic matter intake suggested by the visual kerogen analysis.

The triterpane distributions are quite similar (Fig. 3): both types of sample exhibit abundant 17- β (H), 21- β (H)-hopanes which indicate a low degree of thermal maturity¹⁸. Both the triterpanes present and the occurrence of predominantly biological configurations (that is, 14- α (H), 17- α (H), 20-*R*)¹⁶ of the steranes support the low maturity indicated by vitrinite reflectance and spore colourations, and confirms that the recycled populations do not significantly contribute to the lipid content of these samples.

Comparison of distributions of *n*-alkanoic acids and *n*-alkanols reveals that the black shales contain relatively greater proportions of terrigenous than of marine components of these geolipid classes¹⁴. Because acids and alcohols are more subject to degradation than hydrocarbons, the difference in source character for these geolipid classes again suggests that selective preservation has occurred in the black shales.

The comparisons of organic matter contents confirm that black shales at DSDP Site 530 in the Angola Basin record periods of enhanced preservation of marine, as well as terrigenous, organic material which is superimposed on a low background of residual land-derived material¹⁵. Adjacent green claystones exhibit evidence of burrowing benthic animals and show that bottom waters must have been oxic in Cretaceous times^{3,19}. Because these Cenomanian sediments contain abundant turbidite sequences, the black shales probably represent episodes of downslope redeposition of sediments originally laid down in a midwater anoxic layer which impinged on the African continental slope^{19,20}. Such sediments, rich in organic matter from high marine productivity, must have been rapidly redeposited in the Angola Basin in order to preserve organic substances in an oxic environment. An important implication of this scenario is that deep-ocean black shales can result from local or regional events of short duration which do not involve global oceanic anoxia.

A model of estuarine circulation in the Pliocene Mediterranean based on new ostracod evidence

Dick van Harten

Geological Institute, University of Amsterdam, Nieuwe Prinsengracht 130, 1018 VZ Amsterdam, The Netherlands

The recent discovery of the psychrospheric ostracod *Agrenocythere pliocenica* (Seguenza) in Zanclean marls of eastern Crete¹ expands the reach of early Pliocene deep-oceanic circulation far into the eastern Mediterranean. Current models of Pliocene water-mass circulation, though allowing for the Atlantic psychrosphere to flow freely into the western basin, consider the eastern basin as being largely stagnant^{2,3}. I propose here a new model of estuarine circulation affecting both west and east Mediterranean. This circulation was associated with increased atmospheric humidity and driven by upwelling. The model is compatible with organic-rich sedimentation in parts of the eastern Mediterranean and does not imply an excessively deep or wide connection with the Atlantic.

The term 'psychrosphere'⁴ denotes, in an ecological sense, the cold (temperatures $<8-10^{\circ}\text{C}$), dense bottom-waters of the world ocean that are directly derived from the polar regions. The benthic ostracods inhabiting this environment include a group of highly characteristic genera, among them *Agrenocythere*, whose occurrence is virtually restricted to these waters. The depth at which these ostracods occur is generally $>500\text{ m}$ (ref. 2). In lower latitudes, they live at greater depth than in higher latitudes and upwelling regions⁵. *Agrenocythere* is typical of the upper psychrosphere: recent species are most likely to be found at depths of 1,000-1,500 m; the known depth range of the genus is 400-3,850 m (ref. 6).

In the modern Mediterranean, the temperature of deep bottom-water is $\sim 13^{\circ}\text{C}$ ⁷. Hence, recent faunas of this sea do not exhibit any typically psychrospheric ostracods. However, several such forms are recorded from Pliocene and earlier sediments in the Mediterranean region⁸. Figure 1 shows *A. pliocenica* found in Crete¹ which supports an earlier, doubtful identification of a single specimen in the Zanclean of DSDP Site 378 in the south Aegean⁸. All other spots where this species has been found lie much more to the west⁸⁻¹⁰; Sicily and southern peninsular Italy are the easternmost localities known so far. This new find eliminates any doubt that Pliocene psychrospheric circulation did press far into the east Mediterranean.

A. pliocenica first appeared in the Mediterranean in the *Globorotalia margaritae* zone (see Fig. 2 for the epochs, stages and biozones mentioned in this paper). In Italy, this species ranges up to the early Pleistocene¹. In Crete, we have found it

Fig. 1 *A. pliocenica* (Seguenza) from Zanclean marl (*G. margaritae* zone), Xerokambos, southeastern Crete, Greece. Left valve of a male. Length of specimen 1.4 mm.

Fig. 2 Shows the relation of epochs, stages and biozones mentioned in the text. The Zanclean is intended to be synonymous with the Tabianian used by other authors to denote the earliest part of a bipartite Pliocene.

so far only in samples referable to the *G. margaritae* zone and possibly the *G. margaritae-G. puncticulata* concurrent-range zone. Psychrospheric conditions, although lasting into the Calabrian in Italy, do not seem to have reached the Zanclean-Piacenzian boundary in Crete.

At present, psychrospheric waters cannot enter the Mediterranean because the sill of the Strait of Gibraltar is too shallow (~320 m). To explain the psychrospheric influence in the Pliocene west Mediterranean, it has been suggested that a relatively wide and deep gateway lay between Spain and Morocco⁵. The sill of the connection with the ocean must indeed have been deeper than it is now, although it need not have been much deeper. Assuming dynamic circulation, a depth of 500–1,000 m must be sufficient to allow the uppermost, cold, deep water layers to pass. The width of the connection is difficult to judge, but it seems unnecessary to claim the existence of a true gateway.

The Sicilian Ridge, the shallow sill between Italy and Africa, divides the Mediterranean into a western and an eastern basin. The sill depth is now ~400 m. But the suggestion is that in the early Pliocene the Ridge was a high-standing barrier to deep circulation and thus encouraged stagnancy and the formation of organic-rich deposits in the eastern basin^{3,11}. This is inconsistent with the present evidence for psychrospheric circulation. The early Pliocene palaeodepth of the sill must at least have been equivalent to that of the strait into the ocean.

Participation of the psychrosphere in the circulation of the Pliocene Mediterranean can be inferred from the mere presence of benthic fauna. Otherwise, the deep water-masses would have stagnated and become uninhabitable through oxygen depletion. The circulation of the Mediterranean is now anti-estuarine (Fig. 3a). The high rate of evaporation, which exceeds the sum of river discharge and precipitation, leads to the formation of dense-surface waters that sink periodically to the bottom (downwelling). The densified Mediterranean water flows out into the Atlantic along the floor of the Strait of Gibraltar. Nearer the surface there is an Atlantic countercurrent which compensates for evaporation⁷. Assuming there is a sufficiently deep connection with the ocean, an estuarine pattern with deep water coming in and surface water going out is the simplest model to include the Atlantic psychrosphere in the Mediterranean circulation (Fig. 3b): upwelling can provide the drive for such a system in much the same way as downwelling operates the modern circulation.

The precondition for estuarine circulation is that the surface waters stay less dense than the deeper waters. This requires a stable pycnocline in the water-column in the form of either a halocline, thermocline, or thermohalocline. Evaporation tends to oppose this by making the surface water both saltier and cooler. An estuarine model therefore requires relatively high atmos-

Fig. 3 Mediterranean watermass circulation: paired vertical arrows show schematically the relation of evaporation (open arrows) and fresh-water input by precipitation and river discharge (solid arrows). a, Modern-type anti-estuarine system: surface waters become locally dense and well down, eventually leaving the Mediterranean along the floor of the Strait of Gibraltar; surface currents bring in water from the Atlantic. b, Estuarine system as proposed for the Pliocene and earliest Pleistocene of southern Italy and part of the early Pliocene of Crete: Atlantic upper psychrospheric waters enter the Mediterranean under the influence of a pressure gradient; bottom-waters well up locally and mix with less dense water near the surface; surface currents are directed towards the Atlantic.

pheric humidity to suppress evaporation and promote precipitation. More precipitation leads to increased runoff which, in its turn, could contribute to a primary halocline in parts of the Mediterranean.

The presence of less dense waters in the Mediterranean water-column sets up a pressure gradient with the ocean. If the connection is deep enough, Atlantic psychrospheric waters will enter along this gradient. For these waters to participate in the Mediterranean circulation, upwelling is necessary: wind-driven upwelling most likely occurred in areas off the north coast under the influence of prevailing north winds. Such winds would have tended to move the upper water-layers to the west by Ekman transport. Thermohaline, density-driven upwelling, if at all significant, was probably limited to the easternmost parts where the ocean-derived deep waters had had maximum opportunity to absorb heat.

Estuarine Mediterranean circulation associated with a very warm and humid climate was suggested earlier for the *Sphaeroidinellops* acme-zone¹². Faunas of this zone show an unusual abundance of the planktonic foraminifer *Sphaeroidinellops*³. Similar non-spinose foraminifera with thick tests are known today to prefer deeper water¹³. The abundance of such forms in the earliest Pliocene supports the existence of a halocline with the upper layers too low in salt to be inhabited by marine plankton (S. R. Troelstra, personal communication).

From the occurrence of Taxodiaceae pollen it was recently concluded that humid climatic conditions and rainy summers prevailed in the early Pliocene of the northwest Mediterranean area^{14,15}. An important change, heralding an evolution towards modern seasonal fluctuations (dry summers and wet winters) occurred at the Zanclean-Piacenzian boundary (~3.2 Myr)¹⁵: summer aridity, inferred from the extinction of Taxodiaceae, stabilized diachronously over the Mediterranean region; stability was reached in the Piacenzian in southern France and in the Calabrian in Italy¹⁴. The 3.2 Myr climatic change is also reflected in the oxygen isotope curve of DSDP Site 132 in the Tyrrhenian where it was tentatively associated with increased evaporation relative to precipitation¹⁶.

Sedimentary manifestations of the proposed upwelling might be found in several organic-rich layers or sapropels that have been reported from the early Pliocene of the east Mediterranean, especially at DSDP Site 378 (ref. 17). These sapropels tend to differ from those of the Messinian, late Pliocene, and Quaternary by being relatively low in organic material and burrowed and by containing benthic fauna. They might reflect boosted primary productivity associated with the upwelling of nutrient-rich water from the bottom, rather than complete anoxia due to basin-wide stagnancy¹¹.

Psychrospheric bottom conditions apparently lasted much

longer in Italy than in Crete. At present we can only speculate as to their cause. Considering the similar diachronous summer-aridity stabilization in Italy and France, differential climatic effects may seem a probable cause but direct palynological evidence for this from the east Mediterranean is still lacking. Alternatively, changes in the sea-bottom topography, for instance a rising of parts of the Sicilian Ridge, may have obstructed some deep circulation routes while leaving others unimpaired.

The model outlined here needs further critical testing. Topics to be investigated especially include the climatic history of the east Mediterranean and the relation of Mediterranean organic-rich sediments to upwelling.

I thank Dr Richard H. Benson and Mr Jeroen M. Peters for critical reading of the manuscript and comment. The scanning electron micrograph was made in cooperation with 'Werkgroep SEM', University of Amsterdam.

Potassium-selective single channels in guard cell protoplasts of *Vicia faba*

J. I. Schroeder*, R. Hedrich† & J. M. Fernandez*

* Department of Membrane Biophysics, Max-Planck-Institut für biophysikalische Chemie, D-3400 Göttingen, FRG
† Pflanzenphysiologisches Institut, Universität Göttingen, D-3400 Göttingen, FRG

In plants, stomata control the gaseous exchange between the intercellular spaces of the leaf and the atmosphere. Fluxes of ions, in particular potassium fluxes, across the membranes of the guard cells produce changes in turgor of the guard cells which in turn result in the opening and closing of the stomatal pore^{1,2}. The molecular mechanisms involved in the uptake or release of ions in guard cells are poorly understood². Cell-free membrane patches of the plasmalemma, isolated following patch-clamp techniques³⁻⁵, allow, for the first time in higher plant cells, the separation of the electrical properties of the plasmalemma from those of the tonoplast. We have applied these techniques to study the properties of single-ion channels in the plasmalemma of guard cell protoplasts of *Vicia faba* (broad bean). Predominantly a cation-selective channel was observed, which showed a high selectivity for K⁺, with a permeability ratio P_{K^+}/P_{Na^+} of 11:1 and a single-channel conductance of 37 pS ($=37 \times 10^{-12} \Omega^{-1}$) in symmetrical 225 mM KCl solutions. We estimate that this K⁺ channel contributes significantly to the uptake and release of K⁺ by guard cells during stomatal movement.

Guard cell protoplasts were isolated from the lower epidermis of 3-week-old bean leaves (*Vicia faba* Weisskeimige Hang-down). Epidermal strips were exposed for 60-90 min to 2% cellulase (Rohment CT; Röhm), 0.5% pectinase (Rohment P; Röhm), 0.4 M mannitol and 1 mM CaCl₂. Purified guard cell protoplasts were obtained after 2 h, including the time required

Fig. 1 *a*, Schematic diagram of all four patch-clamp recording configurations³, applied to guard cell protoplasts. Upper panel: high-resistance seals between the pipette and the membrane are established when the fire-polished electrode tip is pressed against the surface of the membrane and suction is applied to the inside of the pipette (cell-attached recording mode). The mechanical stability of the seals allows small membrane fragments to be torn off the cell by drawing the pipette away from the cell. This procedure leaves an intact patch of membrane spanning the pipette tip, resulting in an inside-out patch. The cytoplasmic face of the plasmalemma is exposed to the bath solution. Lower panel: an outside-out patch is obtained when the membrane patch is disrupted by a pulse of suction before pulling off the pipette. The correct sidedness of these patch configurations has been confirmed in numerous experiments on animal cells with channels of known asymmetry³. *b*, *c*, Recordings of K⁺-selective channel currents in an inside-out membrane patch. Discrete open-closed state transitions of single-channel currents can be seen. The membrane was held at $E_m = +40$ mV and stepped by voltage pulses to potentials ranging from +90 mV to -80 mV. The voltage pulse duration was 100 ms. In all records the pulse starts at the upward-pointing arrow and stops at the downward-pointing arrow. Membrane potentials are specified as the potential on the cytoplasmic side of the membrane relative to that on the extracellular side of the membrane during the voltage pulse. Leakage and capacitive currents were subtracted at each potential, using records in which no channel activity was visible. *b*, In symmetrical high K⁺ solutions (225 mM KCl) the single-channel currents are outward at +40 mV and +90 mV (upward deflections of trace). Currents are inward at -40 mV and -80 mV. Note the increase in noise when the channels are open¹⁹. The reversal potential of channel currents is close to 0 mV. Note that on the 0 mV and -80 mV traces, a channel opened before the voltage pulse was turned on and the membrane potential was still +40 mV. When the pulse was turned on, the single-channel current vanished in the 0 mV trace. *c*, After K⁺ was replaced by Na⁺ in the bathing medium (facing the cytoplasmic face of the membrane), the reversal potential shifted to almost +80 mV. A channel was open when the pulse was turned on in the +90 mV trace. All currents are inward from +40 to -80 mV. These data indicate a high selectivity of the channel for K⁺ over Na⁺. Solutions: extracellular (pipette; in mM): 225 KCl, 2 MgCl₂, 1 CaCl₂, 3 KOH, 10 HEPES, 80 D-mannitol, pH 7.0; intracellular (bath): in *b*, same as pipette; in *c*, 225 NaCl, 2 MgCl₂, 1 CaCl₂, 3 NaOH, 10 HEPES, 80 D-mannitol, pH 7.0. All solutions were adjusted to a final osmolarity of $\pi = 500$ mmol kg⁻¹, by adding D-mannitol. Osmolarities were measured with a vapour pressure osmometer (Wescor 5100 C). Temperature 22-25 °C. Control of membrane potential and the measurement of currents were performed with an EPC-7 patch-clamp (List Electronic) and low-pass-filtered at 1 kHz with an 8-pole Bessel characteristic. Data were sampled and stored on a PDP-11/23 minicomputer operating on-line.

for incubation, filtration through a 20 μ m nylon net and two centrifugation steps (60g and 45g). They were suspended in 0.5 M mannitol, 1 mM CaCl₂, stored on ice and used for experiments within 6 h after isolation.

High-resistance seals (>10 G Ω) between the fire-polished tip of the recording pipette and the plasmalemma were established, allowing high-resolution recordings of single-channel currents³. The best results for seal formation were obtained within the first 2 h after protoplast isolation and using small pipettes (tip resistance >3 M Ω)⁶. Techniques well established in animal

Fig. 2 Amplitude of single-channel currents as a function of membrane potential in three cell-free membrane patches (two outside-out patches, one inside-out patch). The three curves were determined by least-squares regression analysis of data in the given intervals. Outward currents have a positive sign. Middle curve: ●, □ × (× is inside-out patch), data from patches in symmetrical 225 mM KCl solutions. The I - V relationship is approximately ohmic between -60 mV and $+60$ mV. The slope reveals a conductance of 37 ± 4 pS. Left curve and top left insert: The insert shows an outside-out patch spanning the pipette tip. +, - Data from the same two outside-out patches after the bath solution was changed to 225 mM NaCl as in Fig. 1c. The reversal potential of single-channel currents shifted to -61 mV (see text). The slope conductance of single-channel currents was reduced to 22 ± 2 pS (-100 mV to -20 mV). Right curve and bottom right insert: *, Data from inside-out membrane patch after the bath solution (facing the cytoplasmic membrane side) was changed to 225 mM NaCl. The reversal potential shifted to $\sim +78$ mV, corresponding to a permeability ratio P_K/P_{Na} of 21:1. The single-channel conductance was fitted to 19 pS between -10 mV and $+140$ mV. Temperature 22 – 25°C .

physiology were used to produce cell-free membrane patches with either the cytoplasmic membrane face (inside-out patch) or the external membrane face (outside-out patch) exposed to the bathing medium^{3,4} (Fig. 1a). Single-channel current could be studied in these configurations, while defining ionic conditions on both sides of the membrane (Fig. 1b, c).

The most frequent ion channel observed was a K^+ -selective channel (Fig. 1b, c) which appeared in 90% of the patches (patch area 2 – $10 \mu\text{m}^2$). The conductance of this channel depended on the K^+ concentration: in solutions containing 30 mM K^+ on the extracellular and 228 mM K^+ on the cytoplasmic side of the membrane, the single-channel conductance ranged from 20 to 27 pS. The direction of single-channel currents reversed at membrane potentials of $E_m = -50$ mV (reversal potential), corresponding to the Nernst potential for K^+ (not illustrated). In symmetrical high K^+ solutions (both pipette and bath containing 225 mM KCl), the single-channel conductance was 37 ± 4 pS ($\pm$ s.d., $n = 3$) (Fig. 2, middle curve).

The permeability ratio of K^+ to Na^+ was determined by measuring the bi-ionic potential^{7,8}. K^+ in the bathing medium was replaced with Na^+ by bath perfusion (Fig. 1b, 225 mM NaCl); this shifted the reversal potential of single-channel currents from 0 mV to approximately -61 mV in outside-out patches. The single-channel current-voltage (I - V) relationship was approximately linear between -100 and -20 mV with a conductance reduced to 22 pS (Fig. 2, left curve). These data indicate a permeability ratio for K^+ to Na^+ (P_K/P_{Na}) of 11:1, after correcting for ionic activities⁹. When K^+ was replaced by Na^+ on the cytoplasmic side of the membrane in an inside-out patch, the reversal potential of single-channel currents shifted to $\sim +78$ mV, indicating an even higher selectivity for K^+ over Na^+ (Fig. 2, right curve).

The kinetics of opening and closing of the K^+ -selective channel were analysed in a patch in which apparently only one

channel was present¹⁰. The mean lifetime of an open channel at $E_m = -60$ mV was 7 ms ($n = 76$) and 10 ms at $E_m = +60$ mV ($n = 60$). The mean closed time of the channel was ~ 13 ms at both -60 mV and $+60$ mV ($n = 103$ and 72 , respectively). These results indicate that the gating mechanism, responsible for the opening and closing of the K^+ -selective channel, is not significantly voltage-dependent and that the channel is open approximately one-third of the time.

The appearance of channels is not an artefact of patch isolation, as the same K^+ -selective channel was observed in the plasmalemma of intact guard cell protoplasts (cell-attached recording mode)³ (Fig. 1a), as judged by the slopes and reversal potentials of the I - V relationships.

K^+ -salts are the predominant osmotically active compounds responsible for changes in the stomatal aperture in over 50 species^{1,2}. Several authors have described a selectivity for K^+ over Na^+ in conjunction with stomatal movement^{11–13}. Guard cells of *V. faba* accumulate between 100 and 300 mM K^+ when the stomata change from the closed to the open state². Furthermore, the relationship between the resting potential of guard cells and external K^+ concentration has been shown to be approximately nernstian^{14,15}. The mean estimated flux of K^+ into guard cells of *V. faba*, determined by several authors², is 10 pmol s^{-1} per cm^2 of plasmalemma surface. These K^+ fluxes are probably associated with membrane potential shifts of up to 60 mV, caused by effectors on stomatal aperture, such as light, CO_2 and abscisic acid^{16–18}. If the membrane potential is displaced 30 mV from the K^+ equilibrium potential, we predict an initial flux through the K^+ -selective channels in a single guard cell of $20 \text{ pmol s}^{-1} \text{ cm}^{-2}$, corresponding to a change in the cell's K^+ concentration of $60 \mu\text{M s}^{-1}$. In this calculation we assumed a channel density of one channel per $15 \mu\text{m}^2$, a guard cell volume of 5 pl , a single-channel conductance of 30 pS, and that the channel is open one-third of the time. This estimate demonstrates that a significant part of K^+ uptake and release by guard cells can be accounted for by passive transport through the K^+ -selective channel studied here.

In addition to the predominant K^+ channel described, several other types of ion channels were seen but have not yet been characterized properly; patch-clamp studies, as used here, may elucidate their physiological function.

We thank Dr E. Neher, Professor K. Raschke, Dr F. J. Sigworth and Professor D. Gradmann for discussions and comments on the manuscript; and U. Brill, W. Lahr, U. Lohmann, M. Odenthal, W. Pagel, A. Sauer, H. Terasa and F. Tiefenau for peeling bean leaves for protoplast preparation. J.M.F. is an Alexander von Humboldt fellow and J.I.S. was supported by the Deutsche Forschungsgemeinschaft.

Benzodiazepines antagonize cholecystokinin-induced activation of rat hippocampal neurones

Jacques Bradwejn & Claude de Montigny*

* To whom correspondence should be addressed

Cholecystokinin (CCK) is a neuropeptide present in the mammalian central nervous system (CNS)¹. In all species studied so far, the highest concentrations of this neuropeptide have been found in the cerebral cortex, the amygdala and the hippocampus²⁻⁵. Five molecular forms of CCK having 39, 33, 13, 8 and 4 amino acid residues have been identified in the CNS, the sulphated octapeptide (CCK₈) being the most abundant form detected^{2,6-8}. Specific CCK binding sites have been demonstrated in the rat, guinea pig and human brain^{9,10}. CCK₈, applied by microiontophoresis to deep cortical neurones and hippocampal pyramidal neurones, has a powerful excitatory effect, whereas the non-sulphated CCK octapeptide has no such effect on these neurones¹¹⁻¹⁶. Low doses of benzodiazepines depress the spontaneous activity of hippocampal pyramidal neurones¹⁷⁻²⁰. We report here that benzodiazepines at very low doses antagonize selectively the CCK₈-induced activation of rat hippocampal pyramidal neurones. This antagonistic action might be involved in the anxiolytic effect of these drugs.

Male Sprague-Dawley rats (200-300 g) were anaesthetized with urethane (1.25 g per kg intraperitoneal) and mounted in a stereotaxic apparatus. Five-barrelled micropipettes were prepared in the conventional manner²¹. The central barrel, filled with 2 M NaCl saturated with Fast Green FCF, was used for extracellular recording of unitary activity. Recordings were obtained from pyramidal neurones of the CA1 and CA3 regions of the dorsal hippocampus. The signal, amplified and displayed in the usual manner, was fed into a differential amplitude

discriminator, generating square pulses from which integrated firing rate histograms were obtained. The side barrels were used for microiontophoresis of the following substances: CCK₈ (10 μ M in 0.2 M NaCl, pH 5); acetylcholine chloride (20 mM, pH 4); flurazepam-2HCl (20 mM, pH 4); chlordiazepoxide-HCl (10 mM in 20 mM NaCl, pH 3); Met-enkephalin (0.5 mM in 0.2 M NaCl and 0.01% bovine serum albumin, pH 4.6); L-glutamate (50 mM in 50 mM NaCl, pH 8.0); L-aspartate (50 mM in 50 mM NaCl, pH 8.0). Three side barrels were used for ejection of the test substances and the fourth one, filled with 2 M NaCl, was used for current balancing. Recording sites were marked by passing a -27 μ A current through the central barrel for 20 min, to make a Fast Green deposit, the location of which was verified histologically.

Intravenous (i.v.) administration of flurazepam, lorazepam or diazepam during the activation of 18 hippocampal pyramidal neurones by microiontophoretically applied CCK₈ reversed this activation, whereas the excitatory effects of applications of acetylcholine (ACh) (14 neurones) or Met-enkephalin (7 neurones) were not affected (Fig. 1a). The effect of the three benzodiazepines was the same in the CA1 and CA3 regions. From the dose-response curves of the effect of i.v. lorazepam and diazepam on CCK₈-induced activation (Fig. 2), we calculated the 50% effective dose (ED₅₀) to be 32.6 ± 2.8 (mean $\pm$ s.e.m.) and 106.5 ± 18.6 μ g per kg for lorazepam and diazepam, respectively.

To verify further the selectivity of benzodiazepines for CCK₈ and to determine whether they were reversing CCK₈-induced activation by a direct action on the pyramidal neurone recorded, flurazepam or chlordiazepoxide, two water-soluble benzodiazepines, were applied microiontophoretically during the activation of CA1 or CA3 hippocampal neurones by applications of CCK₈ (40 neurones), Met-enkephalin (14 neurones), glutamate (8 neurones) and aspartate (8 neurones). Microiontophoretic applications of either benzodiazepine reversed the CCK₈-induced activation of pyramidal neurones but not that produced by ACh, Met-enkephalin, glutamate or aspartate (Fig. 1b-d).

As a preliminary investigation of the specificity of this antagonism for benzodiazepines, haloperidol (5 mg per kg), an

Bars indicate duration of microiontophoretic applications, for which the current is given in nA. The time scale in *e* applies to all the traces. CCK, cholecystokinin-8; ACh, acetylcholine; mENK, Met-enkephalin; FLU, flurazepam; GLU, glutamate; ASP, aspartate.

Fig. 2 Dose-response curve ($\pm$ s.e.m.) of the degree of suppression by i.v. lorazepam (a) and diazepam (b) of the activation of hippocampal pyramidal neurones induced by microiontophoretic application of CCK₈. $r = 0.94$, $P < 0.001$ for lorazepam; $r = 0.82$, $P < 0.001$ for diazepam.

antipsychotic drug, phenobarbital (10 mg per kg), an anticonvulsant barbiturate, and meprobamate (20 mg per kg), a non-benzodiazepine anxiolytic drug, were administered i.v. during the activation of CA3 pyramidal neurones by CCK₈. None of the three non-benzodiazepine drugs affected the CCK₈-induced activation in the 10 experiments performed.

To ascertain that benzodiazepines antagonize CCK₈-induced activation via their specific receptors^{22,23}, we used the imidazodiazepine Ro 15-1788, a benzodiazepine antagonist²⁴. Ro 15-1788 (3.5 mg per kg i.v.) completely blocked the effects of microiontophoretic applications of flurazepam and chlordiazepoxide and of the i.v. administration of lorazepam (100 µg per kg) on CCK₈-induced activation in all six rats tested (Fig. 1d). Moreover, in four other experiments, Ro 15-1788 (3.5 mg per kg i.v.) completely reversed the antagonism of the CCK₈-induced activation produced by microiontophoretic application of flurazepam and i.v. lorazepam (not shown).

This is the first electrophysiological demonstration of the antagonism of the action of a neuropeptide on CNS neurones by benzodiazepines. The present data do not allow any conclusion regarding the molecular mechanism underlying the antagonism by benzodiazepines of the neuronal activation by CCK₈. The selectivity of the action of benzodiazepines for CCK₈-induced activation is indicated by their inability to affect, when administered either intravenously or microiontophoretically, the excitatory effects of another peptide, Met-enkephalin, of ACh and of two putative neurotransmitter amino acids, glutamate and aspartate. Benzodiazepines have been shown to antagonize the excitatory action of kainate on CA1 hippocampal pyramidal neurones²⁵. However, doses more than 30 times greater than those used here are required to reduce kainate-induced activation²⁵; moreover, the activation of CA3 pyramidal neurones by kainate is not antagonized by benzodiazepines²⁵ whereas the excitatory action of CCK₈ is blocked equally well by benzodiazepines in the CA1 and CA3 regions.

The activity of all four benzodiazepines tested in the present study (flurazepam, diazepam, lorazepam and chlordiazepoxide) suggests that the ability to antagonize CCK₈-induced activation is a property common to all drugs of this class. The inactivity of the three anxiolytic non-benzodiazepine drugs tested (haloperidol, phenobarbital and meprobamate) constitutes a preliminary indication that this property might be specific to benzodiazepines. That the antagonism of CCK₈-induced activation might be a property common to, and specific for, benzodiazepines is fully consistent with the prevention and the reversal by Ro 15-1788, a specific 'neuronal' benzodiazepine antagonist, of the effect of benzodiazepines on CCK₈-induced activation²⁶. As there is strong evidence that the activation of the neuronal type of benzodiazepine receptors mediates the anxiolytic effect of benzodiazepines^{27,28}, this suggests that the antagonism of CCK₈ action by these drugs might be involved in their therapeutic effect. The extreme potency of benzodiazepines in blocking CCK₈-induced activation is consistent with this hypothesis.

It is indeed striking that the ED₅₀ for lorazepam (32 µg per kg) and diazepam (106 µg per kg) found here are very close to the most widely prescribed single doses of 1 mg lorazepam and 5 mg diazepam (equivalent to 15–20 µg per kg and 75–100 µg per kg, respectively, for an adult of average weight) in the treatment of anxiety. Moreover, the ratio of the potencies of lorazepam and diazepam found here is very close to that of their clinical anxiolytic activities. Finally, the high density of CCK₈ in the cerebral cortex and in limbic regions such as the hippocampus and the amygdala^{2–4} makes this neuropeptide a suitable candidate for mediating the selective anxiolytic effects of benzodiazepines. As benzodiazepine receptors are coupled with γ -aminobutyric acid (GABA) receptors²⁹, there is a need to investigate the involvement of GABA in mediating the selective suppression by benzodiazepines of CCK₈-induced activation.

We thank W. Haefely for providing us with Ro 15-1788, G. Dubé for typing, and D. Cyr and G. Filosi for preparing the illustrations. C. de M. is a Scientist of the MRC of Canada and J.B. a Fellow of the Fonds de la Recherche en Santé du Québec.

Immunohistochemical localization of endogenous nerve growth factor

R. A. Rush

Department of Human Physiology and Centre for Neuroscience, Flinders University of South Australia, Bedford Park, South Australia 5042, Australia

Nerve growth factor (NGF) has been proposed as a trophic molecule essential for the development of sympathetic and primary sensory neurones^{1,2}. In newborn mice and rats, administration of nerve growth factor results in an increase in the number of surviving neurones^{3,4}, whereas administration of antiserum to NGF decreases neuronal survival^{5,6}. Thus it has been proposed that the factor is produced and secreted by the relevant target tissues to provide trophic support for the ingrowing nerves^{1,7}. The site of synthesis of nerve growth factor is still unknown, and it has been emphasized

Fig. 1 Anti-NGF immunohistochemistry in the rat iris. *a*, The absence of stain in the non-cultured iris; *b*–*e*, the presence of stain in cells clustered into bundles following 4 or 6 days culture. Irises were cultured for 4 (*b*, *d*) or 6 (*c*, *e*) days in Eagle's basal medium containing 10% fetal calf serum and exposed to a humidified 5% CO₂/95% air atmosphere. After incubation the irides were removed, freeze thawed and stretched on polyornithine-coated glass slides and allowed to dry for at least 30 min at room temperature. Antiserum, prepared against mouse salivary gland NGF (electrophoretically pure), was diluted 1 in 4,000 in phosphate buffered saline (PBS) pH 7.4 containing 1% sheep serum and applied to the stretched tissues. Following 48 h incubation at 4 °C, the antiserum was removed and replaced by several changes of PBS. Fluorescein-labelled anti-rabbit IgG (Wellcome, Sydney) was used at a dilution of 1:100 and applied for 1 h then washed from the tissue before mounting. Scale bar, 10 μ m.

that a precise physiological role for the molecule cannot be ascribed until the cell types that produce it are known^{7–9}. I report here the use of immunohistochemistry to localize endogenous NGF in the rat iris, a tissue in which there is sound biochemical evidence for the production of NGF activity¹⁰. Surprisingly, the results reveal that NGF can be detected readily in Schwann cells, but not in smooth muscle cells of the iris when it is sympathetically denervated or cultured.

Irises from adult albino rats (250–300 g body weight) of both sexes were used. After culture for four or six days in Eagles basal medium supplemented with 10% fetal calf serum, irides were removed, freeze-thawed and stretch-mounted on glass slides. Specific stain was clearly visible in all regions of the iris confined to discrete clusters of cells (Fig. 1). The distribution of these cells was similar to that of nerve fibres and bundles throughout the normal iris. Although many labelled cells were clustered in large bundles, individual fusiform cells were also

Fig. 2 Immunohistochemistry in the 6-day cultured rat iris. *a*, Absence of stain in tissue treated with pre-immune serum. *b*, *c*, Presence of stain in degenerating nerve fibres treated with dopamine β -hydroxylase antiserum. *d*–*g*, Presence of stain in strings of single cells stained with nerve growth factor antiserum. Arrows, nuclei discernable by the absence of stain. Staining procedure as for Fig. 1. Scale bar, 10 μ m.

present and were joined end-to-end in long strings with nuclei easily discernable by the absence of stain (Fig. 2). The resolution of the light microscope did not allow the exclusion of stain in degenerating nerve fibres. Even after four days of culture there were a few fragmented sympathetic nerve fibres present that could be visualized by immunohistochemistry with antiserum to dopamine β -hydroxylase¹¹ (Fig. 2). At no stage was anti-NGF stain visible in any smooth muscle fibres; irides that were processed without prior incubation gave negative results (Fig. 2). Cultured and non-cultured irides treated with pre-immune serum were also negative (Fig. 1). Identical results were seen in tissues fixed in picric acid solution prior to staining (Fig. 3). The specificity of the nerve growth factor antiserum was tested (Fig. 3); absorption of the antiserum with NGF-coupled beads blocked the immunohistochemical stain whereas absorption with insulin-coupled beads had no effect. Furthermore, the immunohistochemical stain could be demonstrated using dialysed antibody eluted from the NGF-coupled beads with 1 M acetic acid (Fig. 3).

Irises were next examined following removal of the ipsilateral superior cervical ganglion ten days previously. The effectiveness of sympathetic denervation was demonstrated in half of the iris by the absence of fluorescent nerve fibres following treatment with glyoxylic acid to induce catecholamine fluorescence¹². The remaining half of the iris was stained with NGF antiserum. The distribution of stain was similar to that seen after culture, although both the intensity of the stain and the number of positive cells was reduced considerably (Fig. 4). Contralateral irides treated with the antiserum were negative.

The results presented here provide the first histochemical evidence for the cellular localization of endogenous NGF outside the salivary gland. It is important therefore to examine the authenticity of the antisera used. The major antiserum was raised in rabbits against electrophoretically pure mouse salivary gland nerve growth factor prepared by the method of Mobley *et al.*¹³ (Fig. 4). The purified protein was active in the 1–10 ng ml⁻¹ range, tested by supporting dissociated chick sympathetic

Fig. 3 Immunohistochemistry in the 6-day cultured rat iris. *a*, Absence of stain in an iris treated with antiserum previously absorbed with NGF-Sepharose; *b*, the presence of stain after treatment with whole antiserum; *c*, the presence of stain after treatment with antiserum absorbed with insulin-Sepharose; *d*, the presence of stain after treatment with antibody eluted from the NGF-coupled beads. Irises in *a*, *c* and *d* were fixed after freeze-thaw treatment and prior to staining in picric acid solution for 30 min (150 ml of saturated picric acid solution in 850 ml of PBS, pH 7.4); the iris in *b* was stained without prior fixation as described in Fig. 1.

Methods: Absorption of the antibody with solid phase antigen was performed as follows. Antiserum diluted to 1 in 4,000 was added to 100 μ l Sepharose 4B (Pharmacia) coupled to either NGF or insulin and incubated for 30 min at 37 °C in a shaking water bath. The supernatant was then removed from the beads and used immediately for immunohistochemistry. Purified antibody was eluted from the NGF-Sepharose with 1 M acetic acid and dialysed against PBS before use at a final protein concentration of 2.5 μ g ml⁻¹. Coupling of NGF and insulin to epoxy-activated Sepharose 4B was carried out according to the manufacturer's recommendations using 2 mg of each protein with 0.5 g of lyophilized gel. Scale bar, 10 μ m.

neurons in culture, elevating ornithine decarboxylase activity in newborn rat superior cervical ganglia and in increasing the number of surviving neurons in sympathetic ganglia when administered to developing chick embryos. The resulting antiserum was monospecific against NGF, shown by immunoelectrophoresis against both the purified factor and crude homogenates of male mouse salivary glands; it also stains granular duct cells in this tissue (Fig. 4). This antiserum blocks the survival of sympathetic neurons cultured in the presence of NGF¹⁴. Antiserum and commercial antibodies (Laref, Switzerland), purified by chromatography on an NGF affinity column, gave identical results whereas normal sera from several different rabbits gave negative results. Thus the staining in the figures is

Fig. 4 *a-d*, Evidence for specificity of antiserum to NGF; *e-h*, NGF immunohistochemistry in the sympathetically denervated iris. *a*, Electrophoresis of purified mouse salivary gland nerve growth factor on 12.5% polyacrylamide discontinuous gels in SDS according to the method of Laemmli and Favre²⁰ with a protein load of 30 μ g. *b*, 20 μ g purified NGF on a 30% polyacrylamide gel, pH 10.3, according to the method of Smith, Varon and Shooter²¹. Arrows, position of the origins and dye fronts. *c*, Immunoelectrophoresis against crude mouse salivary gland extract. Electrophoresis was carried out on Corning Universal electrophoretic agarose film (Corning) in 0.065 M barbital buffer, pH 8.6 for 45 min at 200 V with constant cooling. Under these conditions, mouse salivary gland 2.5S NGF does not migrate significantly from the origin. The film was stained after washing with Coomassie blue. *d*, Immunohistochemical localization of NGF in submaxillary gland of male mouse. Anaesthetized male mice were perfused with a solution of 4% paraformaldehyde in 0.1 M phosphate buffer, pH 7.4, the submaxillary glands removed, cut into small blocks and immersed for 3–4 h in the same fixative. The tissue blocks were then rinsed overnight in 5% sucrose in 0.1 M phosphate buffer pH 7.4 and sectioned at 10 μ m on a cryostat. Sections were stained for 48 h at 4 °C with anti-NGF serum diluted to 1 in 4,000 as described in Fig. 1. The fluorescent stain was most intense in apical regions of granular duct cells and absent in acinar cells. *e-h*, fluorescent cells stained with anti-NGF in irides sympathetically denervated 10 days previously. Scale bar, 10 μ m.

probably a result of the interaction of NGF antibodies with an endogenous NGF-like molecule.

The staining present in denervated or cultured irides is localized to a small proportion of the total cells present that are confined to nerve fibre tracts. I suggest here that these are Schwann cells and possibly associated nerve fibres. In the absence of electron microscope evidence, there are several rea-

sons for this conclusion. First, the stained cells clearly are not smooth muscle fibres as their morphology and distribution are distinct from these cells. Second, their morphology is identical to Schwann cells and they are arranged either in clusters or as elongated single cells in bundles resembling nerve fibre bundles. Third, although fibroblasts are present in nerve bundles, their total number is only about 5% of the number of Schwann cells¹⁵. It is unlikely that fibroblasts would be confined to nerve bundles and yet no isolated stained cells were observed outside the bundles. However, this does not exclude the possibility that some positive cells are fibroblasts. Finally, the production of NGF by purified cultures of Schwann cells^{16,17} and isolated peripheral nerve segments¹⁸ is established clearly.

Although it is clear that the anti-NGF stain is associated with nerve tracts throughout both the radial and sphincter muscles, it was not possible to establish which type of nerves are involved. Specific stain was present in both fine nerve tracts and thick bundles; the density of the fibre tracts stained throughout the iris was only slightly less than the density of sympathetic fibres in a non-cultured iris revealed by glyoxylic acid-induced catecholamine fluorescence. In these cultured irides the nerve axons and terminals detached from their cell bodies are degenerating; immunohistochemical localization with dopamine β -hydroxylase antiserum has confirmed that many of the sympathetic nerve fibres have been lost. However, experiments are currently in progress to double-label tissues with NGF and substance P, dopamine β -hydroxylase or choline acetyltransferase antisera to discover whether sensory, sympathetic or parasympathetic fibres are involved.

The production of NGF by Schwann cells in the denervated iris suggests that damaged nerves receive trophic support in the old fibre tracts during regeneration. It also suggests that after injury the nerve returns to an embryonic-like sensitivity. Certainly, regenerating sympathetic nerves are sensitive to NGF⁴, whereas intact nerves in the mature animal show little response to the factor⁷.

Many target tissues of the sympathetic and sensory nervous systems are known to produce NGF in culture¹⁹. This observation has been used to strengthen the proposal that neuronal death occurs during development as a result of competition between growing axons for NGF secreted from target cells, such as smooth and cardiac muscle fibres. However, extrapolation of the present findings to developing nerves would suggest that the nerves are supported during the period of axonal outgrowth by NGF from Schwann cells and that at the time of innervation, the target cells provide a second trophic molecule that is not NGF.

I thank Miss Fiona Renton for technical assistance and Dr Ian Hendry for supplying a sample of antiserum to nerve growth factor. The work was supported by the NH and MRC of Australia and by equipment grants from the MDA of South Australia and the Flinders Medical Centre Research Foundation.

Human T-cell leukaemia virus type III (HTLV-III) is suspected of having a key role in the pathogenesis of acquired immune deficiency syndrome (AIDS)¹⁻⁴. Epidemiological data suggest that AIDS is transmitted by an infectious agent through intimate contact with body secretions, blood or blood products⁵. To maintain haemostasis, many haemophiliac patients depend on commercially prepared clotting concentrates made from large multi-donor plasma pools and are thus at increased risk of developing the disease^{6,7}. We report here that, using indirect membrane immunofluorescence and radioimmunoprecipitation with SDS-polyacrylamide gel electrophoresis, we have detected antibodies to HTLV-III in 30 of 47 (64%) asymptomatic haemophiliacs and in all of three haemophiliacs who either had or soon developed AIDS. Of 34 samples drawn before 1984, 18 (53%) were antibody-positive, whereas of 16 samples drawn during 1984, 15 (94%) were positive ($P \leq 0.002$). These data suggest that exposure to HTLV-III antigens is widespread among asymptomatic haemophiliacs.

We tested samples from 50 haemophiliacs from the New England Area Comprehensive Hemophilia Center in Worcester, Massachusetts; 44 of the patients had haemophilia A and 6 had haemophilia B. All haemophilia A patients had moderate or severe disease and received home infusions of commercial factor VIII concentrate. The samples were collected during 1983-84 from individuals ranging in age from 1 to 69 yr. All were asymptomatic at the time of serum collection, except for a single patient who had clinical AIDS. Two more individuals developed AIDS within 3-6 months (confirmed by the Center for Disease Control).

All sera were initially examined at a 1:4 dilution by indirect membrane immunofluorescence (IMI) on the HTLV-III-infected line, designated H9/HTLV-III, and the uninfected line, designated H9. The method used was that described earlier, except that the cells were inactivated with 2% paraformaldehyde in phosphate-buffered saline as a biohazard precaution before the tests were scored. All 50 samples were subsequently tested using radioimmunoprecipitation with SDS-polyacrylamide gel electrophoresis (RIP-SDS/PAGE). Both uninfected H9 and HTLV-III-infected cells were metabolically labelled for 8 h with ³⁵S-cysteine (100 μ Ci ml⁻¹) according to details described elsewhere^{8,9}.

Of 50 serum samples tested, 33 (66%) reacted with the HTLV-III-infected cells by IMI, but not with the uninfected cells (Table 1, Fig. 1). The same 33 sera showed immunoprecipitation of proteins that migrate in the same position as those regularly detected with reference antiserum to HTLV-III core proteins (provided by Dr R. C. Gallo). Samples from 29 healthy laboratory workers were all negative when tested by both membrane immunofluorescence and immunoprecipitation. The antigens most consistently detected by the 33 positive sera included proteins of molecular weights 24,000 (p24), 41,000 (gp41), 53,000 (p53), 120,000 (gp120) and 160,000 (gp160); these are the proteins that Gallo and colleagues¹⁻⁴ and workers in our laboratory (T. H. Lee and M.E., manuscript in preparation) have found are most frequently detected by human HTLV-III antibodies from AIDS patients. Immunoprecipitation of the gp41, gp120 and gp160 proteins occurred when using a lentil

Fig. 1 A, ^{35} S-cysteine-labelled antigens precipitated from HTLV-III-negative H9 cells (a) and HTLV-III-infected H9 cells (b) by serum samples from asymptomatic haemophiliacs (lanes 1-5, 9-11). Lane 12: a positive control AIDS patient. Lane 13: a negative control (healthy laboratory worker). Lanes 6 and 7: asymptomatic haemophiliacs who developed AIDS within 3-6 months. Lane 8: a haemophiliac AIDS patient. Numbers on the left refer to proteins discussed in the text; numbers on the right refer to molecular weight markers ($\times 10^{-3}$). B, ^{35} S-cysteine-labelled antigens precipitated from HTLV-III-negative cells (a) and HTLV-III-infected H9 cells (b). Serum samples were from: lane 1, a negative control (same as lane 13 in A); lane 2, a positive control AIDS patient (same as lane 12 in A); lane 3, a normal rabbit; lane 4, a reference rabbit antiserum to disrupted HTLV-III³; lane 5, a monoclonal antibody to HTLV-III p24. Numbers on the left refer to molecular weight markers ($\times 10^{-3}$).

lectin-bound, glycoprotein-enriched cell lysate fraction as described earlier, which suggests that these antigens are glycoprotein in nature¹⁰. Seventeen of the serum samples failed to react by either IMI or RIP-SDS/PAGE. Of the 33 serum samples that were positive for antibody to HTLV-III-related glycoproteins, 23 also proved positive for antibody to virus core antigens. p24 is the major virion core protein and p53 is presumed to be the gag gene-encoded polypeptide because, as Gallo and his co-workers¹⁻⁴ and workers in our laboratory (T. H. Lee and M.E., manuscript in preparation) have found, it is readily precipitated with reference antiserum to disrupted HTLV-III. Some haemophiliac samples precipitated a protein of 17,000 molecular weight from H9/HTLV-III cells; this protein is also precipitated by a reference rabbit antiserum to HTLV-III core proteins.

The 50 haemophiliacs tested included three who developed AIDS. All three tested positive by both procedures. Patients who tested positive ranged in age from 4 to 57 yr and included patients with haemophilia A (32 of 44) and haemophilia B (1 of 6). When divided according to the time of sample collection, 18 of 34 (53%) of individuals samples before 1984 were positive whereas 15 of 16 (94%) of those studied during 1984 were positive (one-sided P value ≤ 0.002).

Evidence has been accumulating which suggests that a member of the human T-cell leukaemia retrovirus (HTLV) family is involved in the pathogenesis of AIDS^{1-5,11-17}. Other retroviruses have been linked with naturally occurring immunosuppression and leukaemia in cats¹⁸, and a virus closely related to HTLV

has been associated with leukaemias and lymphoproliferative diseases that have occurred as part of an AIDS-type outbreak in macaque monkeys⁸.

We have previously performed IMI on serum samples of haemophiliacs to test for the presence of antibodies to membrane antigens of cells infected with HTLV-I (HTLV-MA)^{9,11,19}. Haemophiliacs were also tested for antibodies to cytomegalovirus (CMV) and Epstein-Barr virus (EBV)²⁰. Sixty-nine per cent of haemophiliacs had antibodies to EBV and 42% had antibodies to CMV. Approximately 12% of 172 asymptomatic haemophiliacs from four cities tested positive for HTLV-MA; specificity was confirmed with RIP-SDS/PAGE⁹. Because a significant proportion of the haemophiliacs from New York had evidence of antibodies to HTLV-MA before 1980, when AIDS was first described in the United States, it seemed likely that some had been exposed to a conventional strain of HTLV rather than to HTLV-III, the strain that seems to be the aetiological agent of AIDS²¹.

The present results suggest that exposure to HTLV-III is widespread in asymptomatic haemophiliacs. Earlier studies indicated that antibodies to HTLV-I and HTLV-II envelope gene glycoproteins are associated with the development of AIDS^{11,15,22}, presumably because the antibodies are at least partially cross-reactive with HTLV-III proteins¹⁻⁴. Both HTLV-I and AIDS, which is thought to be caused by HTLV-III, seem to be transmitted by blood transfusions and blood products^{15,23-26}. In a previous study, two of three haemophiliacs with AIDS had antibodies to HTLV-MA of type I⁹ and in the

Table 1 Presence of antibodies to HTLV-III in haemophiliacs and healthy laboratory workers

Category	No. tested	HTLV-MA	gp41/gp120/gp160	p24/p53
Haemophilia A	44	32 (73)	32 (73)	23 (52)
Haemophilia B	6	1 (17)	1 (17)	0 (0)
1984	16	15 (94)	15 (94)	13 (81)
Pre-1984	34	18 (53)	18 (53)	10 (29)
Asymptomatic	47	30 (64)	30 (64)	23 (49)
Haemophilia with AIDS	3	3 (100)	3 (100)	0 (0)
Total haemophiliacs	50	33 (66)	33 (66)	23 (46)
Healthy laboratory workers	29	0 (0)	0 (0)	0 (0)

Antibodies to HTLV-MA were determined by IMI; those to gp41/gp120/gp160 and p24/p53 were determined by RIP-SDS/PAGE.

present study two asymptomatic haemophiliacs who subsequently developed AIDS had antibodies to HTLV-III.

The observation that the proportion of asymptomatic haemophiliacs with antibodies to HTLV-III may have increased from 1983 to 1984 deserves further study using sequential samples from the same individuals. As the incubation period for the development of AIDS following blood transfusion has been estimated to range from 10 months to 4 yr²⁶, further studies are needed to evaluate the impact of this observation. Antibody positivity seems to be an indicator of viral infection in most healthy and leukaemic individuals who were naturally exposed to HTLV-I²⁷⁻²⁹ as well as in AIDS patients and healthy male homosexuals exposed to HTLV-III¹⁻⁴. However, it is possible that a significant proportion of asymptomatic haemophiliacs might be exposed only to inactivated HTLV-III rather than to live virus, owing to the manufacturing process involved in the preparation of commercial factor VIII concentrate. In addition,

it is clear that those individuals exposed to factor IX preparations are also at risk for the development of antibodies to HTLV-III. Further studies are needed to determine whether the presence of antibodies to HTLV-III indicates immunization, infection or an asymptomatic carrier state. In addition, the relationship between HTLV-III seropositivity and immunological dysfunction, which has been shown to be widespread among apparently healthy haemophiliacs^{30,31}, requires investigation.

We thank Dr R. C. Gallo for the reference cell cultures and the reference antisera. Significance of herpesvirus immediate early gene expression in cellular immunity to cytomegalovirus infection

Matthias J. Reddehase & Ulrich H. Koszinowski

Federal Research Centre for Virus Diseases of Animals, Tübingen, PO Box 1149, D-7400 Tübingen 1, FRG

Interstitial pneumonia linked with reactivation of latent human cytomegalovirus due to iatrogenic immunosuppression can be a serious complication of bone marrow transplantation therapy of aplastic anaemia and acute leukaemia¹. Cellular immunity plays a critical role in the immune surveillance of inapparent cytomegalovirus infections in man and the mouse¹⁻⁷. The molecular basis of latency, however, and the interaction between latently or recurrently infected cells and the immune system of the host are poorly understood. We have detected a so far unknown antigen in the mouse model. This antigen is found in infected cells in association with the expression of the herpesvirus 'immediate early' genes and is recognized by cytolytic T lymphocytes (CTL)⁸. We now demonstrate that an unexpectedly high proportion of the CTL precursors generated *in vivo* during acute murine cytomegalovirus infection are specific for cells that selectively synthesize immediate early proteins, indicating an immunodominant role of viral non-structural proteins.

According to the static state hypothesis of latency⁹, it is assumed that viral progeny are not produced because the transcription process of the virus is interrupted reversibly at an early stage in the cycle of virus multiplication. In herpes virus infections of permissive cells *in vitro*, analysed in detail for herpes simplex viruses^{10,11}, viral protein synthesis is coordinately regulated and starts with the expression of the 'immediate early' (IE) genes, which are transcribed by host RNA polymerase II. The IE proteins exert important control functions as exemplified by their ability to act as transcriptional activators^{12,13} and they need to be present throughout the replication cycle of herpes-

Table 1 Determination of the IL-CTLp frequency by LDCC

Dose of lectin ($\mu\text{g ml}^{-1}$)	IL-CTLp frequency	No. of IL-CTLp per 10^6 lymphocytes (95% confidence limits)	pMC*
Con A	5	171 (126-215)	0.23
	10	359 (217-502)	0.11
	20	383 (270-495)	0.50
PHA	5	179 (124-234)	0.24
	10	105 (71-140)	0.52
	20	132 (93-171)	0.24

BALB/c (*H-2^d* haplotype) mice were infected at the left hind footpad with 10^5 PFU of tissue-culture propagated MCMV (ATCC VR-194 Smith strain) and 8 days later lymphocytes derived from the draining popliteal lymph nodes were tested for the frequency of activated CTLp in a limiting dilution assay²⁰. In brief, graded numbers of lymphocytes were cultivated for 6 days in 96-well round-bottomed microtitre plates with no addition of viral antigen using medium MEM- α (Gibco) supplemented with 10% vol. fetal calf serum and 20% vol. interleukin-2 containing supernatant. Starting the dilution series with 1×10^5 lymphocytes, 7 log₂ dilution steps were performed with 24 replicate microcultures each. To detect all CTL clones irrespective of their antigen-specificity, the LDCC assay was applied. Various doses of the lectins Con A (Pharmacia) or PHA (Flow Laboratories) were added to 10^3 ⁵¹Cr-labelled, noninfected MEF and CTL at the beginning of a standard 3-h ⁵¹Cr release assay. Precursor frequencies were estimated from the proportion of nonresponding microcultures using the minimum χ^2 (MC)³² and maximum likelihood (ML)³³ methods. Only the results of the MC evaluation are shown.

* Probability calculated by MC method. According to the proposition of Taswell³² an estimate was accepted for a probability of $P > 0.05$ and a ML-MC deviation of $<10\%$.

viruses to permit transcription of the 'early' and 'late' genes¹⁴. Interference with viral transcription at the stage of the expression of IE genes may be involved in establishing viral latency; hence many efforts have been made to clone and map the IE regions of herpesvirus genomes, including those of human^{15,16} and murine cytomegalovirus (MCMV)¹⁷⁻¹⁹. In particular, re-expression of IE genes must be one of the first events in virus reactivation from latency. Selective synthesis of IE proteins leads

Fig. 1 High frequency of LYDIEA-specific IL-CTLp. CTL were generated by *in vitro* interleukin-mediated expansion of *in vivo* activated interleukin-receptive CTLp (IL-CTLp) as outlined in Table 1. Second-passage mouse embryo fibroblasts (MEF) were used as a source of target cells for the ^{51}Cr -release assay. To determine the negative or positive reference frequencies, noninfected MEF were used either in the absence of lectin or with addition of $20\text{ }\mu\text{g ml}^{-1}$ Con A, respectively. Infected target cells after selective expression of immediate early genes (IE-MEF) served to determine the frequency of IL-CTLp specific for the immediate early antigen (LYDIEA) of MCMV. Details of the limiting dilution assay are given in Table 1 and details of the target cell preparation in Table 2.

to the expression of an antigen on the cell surface⁸. This antigen is recognized by CTL and was therefore designated lymphocyte-detected IE antigen (LYDIEA). LYDIEA-specific CTL represented a distinct subset, separate from those CTL recognizing viral structural antigens⁸. The mere fact, however, that during MCMV infection LYDIEA-specific CTL are generated did not allow definite conclusions about the relative significance of the immune response to LYDIEA in comparison with the response to other antigens specified by MCMV.

The solution of two experimental problems was a prerequisite for attempts to evaluate the significance of LYDIEA. First, *in vivo* primed CTL precursors (CTLp) can be detected only after clonal expansion *in vitro* by testing their cytolytically active progeny. This expansion has to be performed in the absence of antigen because restimulation *in vitro* may favour or disfavour the growth of CTLp specific for certain antigens and thereby cause a distortion of the numerical *in vivo* representation of specificities. The expansion of interleukin-receptive CTLp (IL-

CTLp) by interleukin solves this problem as that procedure selects cells only on the basis of differentiation²⁰.

The second problem arises from the fact that progeny CTL are usually detected by their ability to recognize target cells carrying the relevant antigens. This recognition requires sufficient amounts of antigen to be present at the cell membrane²¹. Selective and sufficient expression of LYDIEA can be achieved⁸, but it is not certain in a particular experiment whether each of the other viral antigens is also expressed sufficiently. Therefore, to detect all IL-CTLp generated during MCMV infection regardless of their antigen-specificity, the lectin-dependent cellular cytotoxicity (LDCC) assay was applied. In this assay the T-cell mitogenic lectins concanavalin A (Con A) and phytohaemagglutinin (PHA) are used to bypass the requirement for specific interaction between CTL and target cells^{22,23}. The highest frequency of IL-CTLp was measured when ConA was added at doses of $10\text{--}20\text{ }\mu\text{g ml}^{-1}$ (Table 1). The fact that the corresponding frequency in unprimed mice ranged from 1 in 70,400 to 1 in 91,400 lymphocytes (data not shown) proved that the CTL detected in the lectin-dependent cellular cytotoxicity (LDCC) assay were derived from *in vivo* sensitized precursors. This condition was then used to assess the total frequency of IL-CTLp.

The results of a representative limiting dilution assay are shown in Fig. 1 and those of an independent second experiment summarized in Table 2. The frequency of LYDIEA-specific IL-CTLp present in a draining popliteal lymph node was found to be 1 in 6,600 lymphocytes (Fig. 1) or 1 in 6,900 lymphocytes, respectively (Table 2). This determination was carried out on target cells that selectively expressed high amounts of IE proteins. The selective transcription of IE genes in target cells was achieved by infection in the presence of the translation inhibitor cycloheximide that led to an accumulation of IE RNA. The subsequent release from cycloheximide and further cultivation in the presence of the transcription inhibitor actinomycin D then resulted in an enhanced synthesis of IE proteins and simultaneously prevented further viral transcription^{8,19}.

During noninterrupted (productive) infection, the synthesis of IE proteins is followed by the synthesis of so-called early proteins and, after viral DNA replication, of late proteins which include the major viral structural proteins^{10,24}. Among those especially the glycoproteins of the virion envelope should contribute significantly to the antigenicity of infected cells. Nevertheless, when tested on cells corresponding to the late

Table 2 IL-CTLp frequencies as determined by antigen-specific or lectin-dependent cellular cytotoxicity

Target cell (virus dose; inhibitors)	IL-CTLp frequency	No. of IL-CTLp per 10^6 lymphocytes (95% confidence limits)	pMC
MEF (—; CH-Act.D)	1/166,400	6 (4–8)	0.35
MEF + Con A (—; CH-Act.D)	1/2,700	371 (226–516)	0.27
IE-MEF (0.05; CH-Act.D)	1/6,900	146 (97–195)	0.16
Late-MEF (0.05; -Act.D)	1/11,300	89 (60–118)	0.24
UV-MCMV-MEF (0.05; CH-Act.D)	1/85,300	12 (8–16)	0.35
UV-MCMV-MEF (0.5; CH-Act.D)	1/44,300	23 (12–33)	0.16
UV-MCMV-MEF (5; CH-Act.D)	1/14,900	67 (48–86)	0.08

Second-passage MEF were used as target cells throughout. Infection was performed under centrifugal enhancement conditions³⁴ ($800g$ for 30 min) with the indicated virus dose of infection that is given in plaque-forming units (PFU) per cell as determined in a conventional plaque titration assay. The centrifugation enhances the efficiency of infection by 20- to 80-fold and thus a virus dose of 0.05 PFU corresponds with an effective multiplicity of about 1–4 PFU per cell. At a multiplicity of 100–400 PFU per cell target cells started to disintegrate and therefore the application of higher doses was precluded. For the preparation of IE targets and the appropriate controls, infection and 3 h of cultivation were performed in the presence of cycloheximide (CH, $50\text{ }\mu\text{g ml}^{-1}$). Thereafter, CH was washed out and actinomycin D (Act.D, $5\text{ }\mu\text{g ml}^{-1}$) was added. Only for the preparation of the late-MEF target, infection was carried out in the absence of CH and viral replication was allowed to proceed for 20 h until transcription was stopped by addition of actinomycin D. To test lectin-dependent cytotoxicity, Con A was added during the effector phase at a final dose of $20\text{ }\mu\text{g/ml}$. For mock-infection of MEF, partially purified stock virus ($2 \times 10^8\text{ PFU ml}^{-1}$)²⁰ was diluted with phosphate-buffered saline to a final concentration of $1 \times 10^7\text{ PFU ml}^{-1}$ and then exposed as an 1-mm layer to a 10-min irradiation with a 90 W UV-illuminator at 254 nm. The distance between specimen surface and ultraviolet-screen was adjusted to give an intensity of $30\text{ J m}^{-2}\text{ s}^{-1}$. To control the effect of irradiation on viral protein synthesis³⁵, MEF were infected with the highest dose of virus used in the experiments (5 PFU equivalents per cell) and IE protein synthesis was enhanced by inhibitor treatment. Monoclonal antibody 6/58/1 (to be described elsewhere) was then used to detect IE nuclear antigen by indirect immunofluorescence. Irradiation of virus for 2.5 min ($4,500\text{ J m}^{-2}$) reduced the number of IE antigen positive cells to less than 1% and after 5 min of irradiation viral protein synthesis was abolished in all cells.

stage of viral replication, the frequency of IL-CTLp was only 1 in 12,800 lymphocytes (not depicted in Fig. 1) or 1 in 11,300 lymphocytes, respectively (Table 2).

In addition to *de novo* synthesized antigens, virion proteins or glycoproteins inserted into the cell membrane during the process of penetration can directly account for an antigenicity of MCMV-infected cells. This has been demonstrated previously by infection of cells in the continuous presence of actinomycin D or cycloheximide⁶. Different treatment, mock-infection with UV-inactivated virus, still permits the synthesis of cellular proteins which might be induced by viral structural proteins and could also contribute to target formation. This control is therefore indicated to discriminate between target antigens induced by the IE activity of the viral genome and those antigens whose expression does not require IE protein synthesis. When mock-infection of targets was performed with a dose of ultraviolet-inactivated virus equivalent to the dose of infectious virus applied for preparing the IE target, the frequency was only 1 IL-CTLp in 85,300 lymphocytes (Table 2). This result proved that the high frequency of 1 IL-CTLp in 6,900 lymphocytes, detected with the IE target, was indeed due to the expression of an IE antigen and thus referred to LYDIEA-specific IL-CTLp. This conclusion is further confirmed by the finding that in the absence of viral genome-induced protein synthesis even a hundred-fold increase in the virus dose did not allow to detect the number of IL-CTLp that could be detected with the IE target or with the productively infected target (Table 2).

The total frequency of IL-CTLp in these experiments was found to be 1 in 3,100 lymphocytes (Fig. 1) or 1 in 2,700 lymphocytes, respectively (Table 2). Hence, based on the determination of the total IL-CTLp frequency, the LYDIEA-specific subset comprised 40–50% of all IL-CTLp generated during infection.

The finding that such a substantial proportion of the IL-CTLp recognize an antigen expressed during the IE phase of viral replication was unexpected because transcription at that stage is restricted to only few genes, while extensive transcription from the whole genome occurs at later stages¹⁹.

Three possibilities might explain the high frequency of LYDIEA-specific IL-CTLp: First, the primary T cell specificity repertoire of BALB/c mice may already contain a high relative number of precursors specific for this antigen. There is no approach to test this possibility as limiting dilution experiments have revealed an extremely low frequency of primary CTLp specific for MCMV²⁰ or herpes simplex virus²⁵ and that is why a reliable comparison between particular antigens is not feasible.

Second, the expression of antigens may be different in the tissues of the infected animal than predicted from the productive infection of embryonic fibroblasts *in vitro*. Since in the immunocompetent host MCMV does not replicate at the site of intraplantar infection, whereas after immunosuppression fibroblasts of the footpad tissue are productively infected (manuscript in preparation), the immune system is involved in terminating the *in vivo* viral replication at an early stage. This could imply a preferential sensitization of LYDIEA-specific CTLp and explain the high proportion of LYDIEA-specific IL-CTLp in the draining lymph node. We are now testing the amount of IE gene expression by *in situ* hybridization using cloned viral DNA fragments¹⁹.

Third, the IE antigen may be highly immunogenic. Its molecular identity has first to be defined in order to evaluate this alternative. At present it is known that the expression of LYDIEA requires transcription and translation⁸ and coincides with the synthesis of a phosphorylated but not glycosylated protein of 89,000 apparent relative molecular mass. This protein and its post-translational modification products are the dominant IE proteins located in the nucleus and cytoplasm of the infected cell (G. M. Keil *et al.*, in preparation). Since recognition by CTL must be considered as a *prima facie* evidence for surface localization of an antigen, the actual relationship between these serologically detectable intracellular proteins and the antigen LYDIEA requires further analysis. The presence of

nonglycosylated viral proteins, located predominantly in the nucleus and cytoplasm, coincides with the recognition of infected cells by CTL also in other virus infections such as Epstein-Barr virus²⁶, simian virus 40^{27,28} and influenza virus^{29–31}. In this context it has been suggested that processed products rather than the intact protein may represent the actual antigen³¹ or that the intracellular protein may modify other viral or cellular products²⁹.

Irrespective of the so far unknown molecular identity of LYDIEA, the requirement of IE proteins for the synthesis of viral structural proteins during acute infection or after reactivation from latency raises the possibility of a physiological role of LYDIEA-specific CTL in the surveillance of viral latency. LYDIEA-specific memory-CTL which are present in latently infected mice⁸ could be activated as soon as IE genes are expressed and eliminate recurrently infected cells before the assembly of progeny virions.

Phorbol ester and diacylglycerol mimic growth factors in raising cytoplasmic pH

W. H. Moolenaar, L. G. J. Tertoolen & S. W. de Laat

Hubrecht Laboratory, International Embryological Institute, Uppsalalaan 8, 3584 CT Utrecht, The Netherlands

There is now good evidence that cytoplasmic pH (pH_i) may have an important role in the metabolic activation of quiescent cells^{1,2}. In particular, growth stimulation of mammalian fibroblasts leads to a rapid increase in pH_i (refs 3–6), due to activation of a Na^+/H^+ exchanger in the plasma membrane⁴, and this alkalization is necessary for the initiation of DNA synthesis⁷. However, the mechanism by which mitogens activate the Na^+/H^+ exchanger to raise pH_i is not known, although an increase in cytoplasmic free Ca^{2+} ($[Ca^{2+}]_i$) has been postulated as the primary trigger^{8–10}. We

now present data suggesting that the Na^+/H^+ exchanger is set in motion through protein kinase C, a phospholipid- and Ca^{2+} -dependent enzyme normally activated by diacylglycerol produced from inositol phospholipids in response to external stimuli^{11,12}. Using newly developed pH microelectrodes and fluorimetric techniques, we show that a tumour promoting phorbol ester and synthetic diacylglycerol, both potent activators of kinase C (refs 12–15), mimic the action of mitogens in rapidly elevating pH_i in different cell types. Furthermore, we demonstrate that, contrary to previous views, an early rise in $[\text{Ca}^{2+}]_i$ is not essential for the activation of Na^+/H^+ exchange and the resultant increase in pH_i . Finally, we suggest that an alkaline pH_i shift, mediated by Na^+/H^+ exchange, may be a common signal in the action of those hormones which elicit the breakdown of inositol phospholipids.

Human foreskin fibroblasts (HF cells), HeLa cells and mouse N1E-115 neuroblastoma cells, grown on rectangular glass coverslips, were loaded with the fluorescent pH indicator 2',7'-bis(carboxyethyl)-5,6-carboxyfluorescein (BCECF) by uptake of its membrane-permeable ester¹⁶, and the pH_i -dependent emission intensity from the cells was continuously monitored as described previously^{4,17}. In addition, pH_i was directly measured in large N1E-115 cells by means of a novel type of pH-sensitive intracellular microelectrode (see Fig. 1 legend).

Fig. 1 *a*, Time course of increase in pH_i induced by TPA (200 ng ml^{-1}) in mouse N1E-115 neuroblastoma cells. Subconfluent cultures, attached to a glass coverslip, were deprived of serum for 24 h and loaded with BCECF as described previously⁴. The cells were incubated in HEPES-buffered Dulbecco's modified Eagle's medium (DMEM, pH 7.40) without phenol red and pH_i -dependent fluorescence was measured at 506–532 nm using a Perkin Elmer model 3000 fluorescence spectrometer. The fluorescence of BCECF varies linearly with pH over the range 6.4–7.6 (ref. 17). Temperature was maintained at 32°C. Similar TPA-induced shifts in pH_i were observed in serum-deprived HeLa cells (subconfluent) and HF cells (confluent). *b*, Direct measurement of pH_i and membrane potential (V_m) in large N1E-115 cells (diameter $> 40 \mu\text{m}$), penetrated by a pH-sensitive microelectrode and a voltage-measuring microelectrode, showing rapid recovery of pH_i from a NH_4^+ -induced acid load, and TPA-induced rise in pH_i . pH_i regulation in N1E-115 cells, as in HF cells and HeLa cells, is almost entirely mediated by amiloride-sensitive Na^+/H^+ exchange (refs 4, 17, 32 and W.H.M., unpublished results). The method for constructing pH-sensitive microelectrodes is described below. Solutions were exchanged by rapid perfusion. Other experimental details are essentially similar to those described previously^{33,34}. Final TPA concentration, 200 ng ml^{-1} . External pH 7.40. Temperature, 35°C. *c*, Lack of effect of TPA on pH_i in BCECF-loaded N1E-115 cells maintained in Na^+ -free medium. Na^+ was replaced by bis(2-hydroxyethyl)dimethylammonium. Cells rapidly acidify in Na^+ -free medium, but pH_i immediately recovers after re-addition of Na^+ (see refs 4, 17, 32). *d*, Effects of PDGF (40 ng ml^{-1}), TPA (200 ng ml^{-1}) and monensin ($5 \mu\text{M}$) on pH_i in BCECF-loaded culture of quiescent HF cells. Insulin was present at $5 \mu\text{g ml}^{-1}$ to potentiate PDGF-induced pH_i shift (insulin alone has no effect on pH_i ; ref. 4). Human PDGF ($>95\%$ pure) was added in the presence of $100 \mu\text{g ml}^{-1}$ bovine serum albumin (essentially fatty acid free). *e*, Effect of synthetic OAG ($50 \mu\text{g ml}^{-1}$) on pH_i in BCECF-loaded N1E-115 cells. OAG stock solution in dimethyl sulphoxide (DMSO) was diluted to 1% DMSO with DMEM + $50 \mu\text{g ml}^{-1}$ bovine serum albumin (fatty acid free). A 250- μl aliquot of this OAG solution was then briefly sonicated under N_2 and immediately added to the cells. The final DMSO concentration was 0.1%, which alone had no effect.

Methods: Construction of pH-sensitive microelectrodes: An 8-mm length of pH-sensitive glass tubing (outer diameter 1.0 mm; inner diameter 0.5 mm; Clark Electromedical Instruments) was placed in the centre of a 5-cm piece of insulating lead glass tubing (outer diameter 1.6 mm; wall thickness $<0.15 \text{ mm}$). The coaxial tubes were pulled into two microelectrodes using a horizontal micropipette puller. About 50–60% of the electrodes then contains a sealed pH-sensitive tip with an outer diameter of $<0.5 \mu\text{m}$. Electrodes were first filled with methanol by boiling under reduced pressure at room temperature. Methanol was then replaced with 0.1 M HCl by diffusion. Subsequently, the electrode tips were immersed into a chromic acid cleaning solution for 12–24 h before experimentation. Electrodes were tested for giving a Nernstian response to pH changes (54–58 mV per pH unit) and having resistance of $1\text{--}2 \times 10^9 \Omega$. The speed of response to a sudden pH change of 1 unit was about 15–20 s. Selected electrodes could be stored for a few days (tips in chromic acid) before obvious deterioration. The construction of this novel type of pH-sensitive electrode was found to be much easier than that of the common 'Thomas type' pH microelectrodes³⁵. Further details will be described elsewhere.

Fig. 2 Rapid changes in $[Ca^{2+}]_i$ in HF cells after addition of FCS (10%) (a), PDGF (40 ng ml⁻¹) (b) and TPA (c; trace 1, 50 ng ml⁻¹; trace 2, 200 ng ml⁻¹) at time zero. Quiescent HF monolayers were loaded with quin-2 by incubating them in DMEM containing 50 μ M quin-2 acetoxymethyl ester (Amersham) for 30 min at 37°C and $[Ca^{2+}]_i$ -dependent fluorescence was continuously measured at 339–500 nm (temperature, 32°C). Signals were calibrated essentially as described elsewhere^{26,36}. Resting value of $[Ca^{2+}]_i$ is estimated at 140 nM, while peak values of the FCS and PDGF traces correspond to ~400 and 300 nM $[Ca^{2+}]_i$, respectively.

by the magnitude of the transmembrane Na^+ and H^+ gradients, as pH_i can be increased still further by addition of the Na^+/H^+ ionophore monensin (Fig. 1d). From these results we conclude that TPA, like growth factors^{4–6}, raises pH_i by activating the otherwise quiescent Na^+/H^+ exchanger in the plasma membrane.

If activation of Na^+/H^+ exchange is mediated by kinase C, an alkaline pH_i shift may be expected after addition of an unsaturated diacylglycerol such as 1-oleoyl-2-acetyl-glycerol (OAG; refs 14, 15). In physiological conditions, 1,2-diacylglycerol is produced from hydrolysis of inositol phospholipids and serves as the endogenous activator of protein kinase C^{11,12}. As illustrated in Fig. 1e, addition of 50 μ g ml⁻¹ OAG to N1E-115 cells does indeed induce a rapid alkaline shift in pH_i of at least 0.1 unit. A similar shift was observed in OAG-treated HeLa cells. Other lipid degradation products such as phosphatidic acid and arachidonic acid, a precursor of prostaglandins, were unable to raise pH_i . Furthermore, indomethacin (5 μ M), a potent inhibitor of prostaglandin synthesis, did not affect the pH_i shifts induced by either TPA or PDGF. Various lipid-interacting drugs, such as the phenothiazines, are potent inhibitors of protein kinase C^{20,21}. We found that trifluoperazine (TFP) at 10 μ M produced ~50% inhibition of both the PDGF- and TPA-evoked pH_i shifts in HF cells without affecting basal pH_i levels. (At higher TFP doses the cytoplasm gradually acidified, presumably due to a nonspecific membrane perturbation and consequent H^+ influx.) The above results, together with the fact that growth factors are potent inducers of inositol lipid breakdown^{22,23}, strongly suggest that protein kinase C is responsible for the activation of Na^+/H^+ exchange by mitogens and phorbol ester.

Although the Ca^{2+} ionophore A23187 is incapable of elevating pH_i in fibroblasts⁴, the possibility nevertheless remains that a rapid increase in $[Ca^{2+}]_i$ may have some critical role in Na^+/H^+ exchange activation, as postulated by others¹⁰. We therefore used the intracellularly-trapped fluorescent dye quin-2 (refs 24,

Table 1 Effects of TPA on pH_i

Cell type	Resting pH_i (mean $\pm$ s.e.)	ΔpH_i (relative to control)
HF	7.05 $\pm$ 0.02 (n = 12)	0.16 $\pm$ 0.03 (n = 5)
HeLa	7.18 $\pm$ 0.04	0.17 $\pm$ 0.02 (n = 7)
N1E-115	7.24 $\pm$ 0.03	0.15 $\pm$ 0.02 (n = 8)

Cells were loaded with BCECF and assayed for TPA-induced shifts in pH_i (ΔpH_i) by the K^+ -nigericin calibration method as detailed elsewhere^{4,17}. HF and N1E-115 cells were maintained in serum-free DMEM for 24 h and HeLa cells for 4 h before experimentation. TPA concentration, 200 ng ml⁻¹. External pH , 7.30–7.40. Temperature, 30–32°C. The number of experiments is given in parentheses.

25) to monitor $[Ca^{2+}]_i$ after activation of quiescent HF and N1E-115 cells. Figure 2a, b illustrates typical results from HF cells, the details of which are presented elsewhere²⁶, and shows that fetal calf serum (FCS) and PDGF immediately raise $[Ca^{2+}]_i$ two- to threefold above its resting level of about 140 nM. This mitogen-induced Ca^{2+} signal is initiated without a detectable lag period and peaks within 1 min before slowly declining towards a new steady level. The Ca^{2+} response is not prevented by removal of external Ca^{2+} (ref. 26), indicating that FCS and PDGF act by releasing Ca^{2+} from intracellular stores, probably due to the rapid formation of inositol 1,4,5-trisphosphate²⁷. A qualitatively similar Ca^{2+} signal was observed in serum-stimulated N1E-115 cells (not shown).

By contrast, TPA, at concentrations that evoke a significant pH_i shift, completely fails to raise $[Ca^{2+}]_i$ above basal levels in HF cells (Fig. 2c). At 200 ng ml⁻¹, TPA even induces a slight fall in $[Ca^{2+}]_i$. The apparent inability of TPA to elevate $[Ca^{2+}]_i$ agrees with previous findings in quin-2-loaded lymphocytes²⁴, neutrophils²⁸ and platelets²⁹. These findings demonstrate that although growth factors are Ca^{2+} -mobilizing hormones, an early rise in $[Ca^{2+}]_i$ is not essential for the activation of Na^+/H^+ exchange by external stimuli, and they reinforce the notion that the Na^+/H^+ exchanger is set in motion mainly through activated kinase C. Thus, the simplest and most attractive explanation for our findings is that protein kinase C directly phosphorylates the Na^+/H^+ exchanger on its cytoplasmic face and thereby increases its apparent affinity for intracellular H^+ (see ref. 4).

The results reported here raise the interesting possibility that cytoplasmic alkalization, mediated by Na^+/H^+ exchange, is not restricted to the action of growth factors and tumour-promoting phorbol esters, but that it may commonly occur in response to those hormones and other surface stimulants which trigger the breakdown of inositol phospholipids and thereby activate kinase C. There is indeed some evidence to support this notion: in typical model systems of hormone-induced inositol lipid turnover, such as platelets and neutrophils, the pH_i rises rapidly on activation by physiological stimuli^{30,31}. Further work will be needed to explore the ubiquity of cytoplasmic alkalization in hormone action and to identify the pH_i -dependent responses in different target cells.

We thank Roger Y. Tsien for gifts of BCECF-ester and OAG, Carl-Henrik Heldin for providing pure PDGF, Lilian Joosen for technical assistance and Dr M. J. Berridge for stimulating discussions. This work was supported by grants from the Netherlands Cancer Foundation (Koningin Wilhelmina Fonds).

Stepwise enzymatic dephosphorylation of inositol 1,4,5-trisphosphate to inositol in liver

Diane J. Storey, Stephen B. Shears, Christopher J. Kirk & Robert H. Michell

Department of Biochemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, UK

Many receptors for hormones, neurotransmitters and other signals cause hydrolysis of phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂) and effect a rise in cytosolic Ca²⁺ concentration¹⁻⁷. The inositol 1,4,5-trisphosphate (Ins(1,4,5)P₃) liberated during PtdIns(4,5)P₂ breakdown seems to serve as a second messenger that activates the release of Ca²⁺ from a nonmitochondrial intracellular compartment⁷⁻¹². As expected if it is an important intracellular messenger, Ins(1,4,5)P₃ is relatively rapidly degraded, both within stimulated cells^{13,14} and when added to homogenates of blowfly salivary gland¹⁵ or to permeabilized, but not intact, hepatocytes¹⁰. Here we report that the dephosphorylation reactions responsible for the conversion of Ins(1,4,5)P₃ to free inositol in rat liver are catalysed by two or more enzymes, and that these reactions are distributed between the plasma membrane and cytosol. The Ins(1,4,5)P₃ 5-phosphatase and inositol 1-phosphatase (Ins(1)P) phosphatase of liver appear similar to enzymes described previously in erythrocytes¹⁶ and brain¹⁷.

Rat liver homogenates were incubated with small concentrations of ³²P-labelled inositol phosphates in conditions of ionic composition and pH chosen to approximately mimic those of the cytosol of stimulated cells (for details, see legend to Table 1). Ins(1,4,5)P₃ (labelled in its 4- and 5-phosphate groups), inositol-1,4-bisphosphate (Ins(1,4)P₂) (labelled in its 4-phosphate) and Ins(1)P were rapidly degraded during such incubations, with hydrolysis of Ins(1,4,5)P₃ being the most rapid reaction (Table 1). High-speed centrifugation sedimented a large proportion of the Ins(1,4,5)P₃ phosphatase activity and left most of the Ins(1,4)P₂ phosphatase and Ins(1)P phosphatase activity in the soluble fraction (Table 1). Analysis of the products of Ins(1,4,5)P₃ hydrolysis^{16,18} by a plasma membrane/Golgi-rich membrane fraction recovered from a density gradient separation (as in Fig. 1) showed selective removal of the 5-phosphate (data not shown).

Fig. 1 Distribution of Ins(1,4,5)P₃ 5-phosphatase and various marker enzymes after density gradient centrifugation of a rat liver nuclei-free homogenate. *a*, The distribution of Ins(1,4,5)P₃ 5-phosphatase. *b*, The distribution of marker enzymes for cytosol (inulin), Golgi membranes (galactosyltransferase, galtrans), plasma membranes (leucyl-β-naphthylamidase, LNA), endoplasmic reticulum (arylesterase, arylest), lysosomes (β-galactosidase, β-gal) and mitochondria (glutamate dehydrogenase, GDN). The results shown and the recoveries (see below) are for a single representative experiment. Data are plotted as the percentages of the total recovered activity or component found in each fraction, and values of <0.5% of recovered activity have been omitted from *b* for clarity. **Methods:** Hepatocytes, prepared and incubated as described previously²⁴, were homogenized using N₂ cavitation²⁵ in 0.25 M sucrose containing 3 mM TES (2-([2-hydroxy-1,1-bis(hydroxymethyl)ethyl]amino)ethane sulphonic acid), adjusted to pH 7.4 with KOH; 0.4 ml of a nuclei-free homogenate²⁵ was added to 0.4 ml of homogenization buffer that had been layered on the top of an isoosmotic density gradient of Percoll suspended in homogenization buffer (5.5 ml of density 1.052 g ml⁻¹ above 1.2 ml of density 1.074 g ml⁻¹). Gradients were centrifuged for 15 min at 73,000 g (mean) in a 10 × 10 ml angle rotor. Fractions (214 μl) were recovered, and their components and densities assayed as follows: Ins(1,4,5)P₃ 5-phosphatase (assayed as described in Table 1; recovery of loaded activity in fractions from gradient-85%); inulin (followed in a separate gradient in parallel, after addition of 1.5 μCi ml⁻¹ ³H-inulin to homogenate before centrifugation; 100% recovery); galactosyltransferase (ref. 24; 84% recovery); LNA (ref. 25; 96% recovery) (a large proportion of this enzyme activity distributes with glucagon-stimulated adenylate cyclase, an enzyme concentrated in the hormone-sensitive sinusoidal domain of the hepatocyte plasma membrane²⁵); arylesterase (ref. 24; 96% recovery); β-galactosidase (ref. 26; 111% recovery); GDN (ref. 24; 81% recovery).

Table 1 First-order rate constants for hydrolysis of inositol phosphates in liver preparations, corrected to the enzyme concentrations of the original tissue

Fraction	Ins(1,4,5)P ₃	First-order rate constant (s ⁻¹)			Ins(4)P
		Ins(1,4)P ₂	Ins(1)P		
Homogenate	0.148 ± 0.019	0.018 ± 0.022	0.007 ± 0.001		NA
Soluble	0.035 ± 0.005	0.028 ± 0.004	0.009 ± 0.002		0.0002
Particulate	0.095 ± 0.007	0.004 ± 0.001	0.003 ± 0.0004		NA
Washed particulate	0.065 ± 0.006	0.004 ± 0.0004	0.0009 ± 0.0003		NA

[4-³²P]Ins(1,4)P₂ and [4,5-³²P]Ins(1,4,5)P₃ were prepared as described previously^{15,17}. ³²P-Ins(1)P was produced by phosphodiesterase-catalysed hydrolysis of ³²P-phosphatidylinositol using a soluble liver enzyme preparation (details to be described elsewhere), and isolated by high-voltage electrophoresis²³. Rat livers were cleared of blood by perfusion of 0.25 M sucrose/5 mM Tris (pH 8.0) through the hepatic portal vein under pentobarbital anaesthesia. The livers were removed, homogenized in the same medium in a glass-Teflon Potter-Elvehjem homogenizer (20 strokes, 500 r.p.m.), and the homogenates filtered through a 300-μm mesh and made up to 3 ml per g tissue. Homogenates were centrifuged at 180,000g for 30 min and the supernatant and pellet made up to the volume of the original homogenate (to yield 'soluble' and 'particulate' fractions). Some of the 'particulate' fraction was again centrifuged and resuspended, to yield the 'washed particulate' fraction. The medium used for enzyme incubations comprised (in mM): 10 NaCl, 70 K⁺ glutamate, 30 KCl, 4 MgSO₄, 10 HEPES, 1 EGTA, pH 7.2. Ins(1,4,5)P₃ 5-phosphatase activity in this 'physiological' medium is rather more than half of that in the ionic strength medium used previously¹⁶, both for erythrocyte membranes and liver cell fractions. Incubations were in a final volume of 1 ml, containing 50 μl of the homogenate or cell fraction, and they were continued for an appropriate period (1 min to 4 h) in order to yield a first-order rate constant for the hydrolysis of the phosphate ester being tested. The substrate concentrations were in the ranges 40–300 nM (for Ins(1,4,5)P₃ and Ins(1,4)P₂) and 8–24 μM (for Ins(1)P). Incubations were stopped by adding 100 μl of 12 M perchloric acid containing 1 mM P_i, and released ³²P-P_i was estimated as described previously¹⁶. The values given are the means ± s.e.m. (n = 4). The approximate rate constant for hydrolysis of Ins(4)P is derived from the second exponential (that for ³²P-Ins(4)P) on a prolonged rate curve describing hydrolysis of [4-³²P]Ins(1,4)P₂. NA, not assayed.

On density gradient centrifugation of nuclei-free liver homogenates, the Ins(1,4,5)P₃ 5-phosphatase activity of the particulate fraction was largely associated with fractions of density 1.035 g ml⁻¹; these were rich in plasma membrane and Golgi markers, rather than those of mitochondria, endoplasmic reticulum or lysosomes (Fig. 1). Isolated nuclei showed little Ins(1,4,5)P₃ phosphatase activity (data not shown), and Prentki *et al.*¹¹ have also reported a low Ins(1,4,5)P₃ phosphatase activity in endoplasmic reticulum membranes from an insulinoma-derived cell line. Preliminary studies of highly enriched preparations of plasma membranes and Golgi membranes suggest that most of the Ins(1,4,5)P₃ 5-phosphatase is associated with plasma membranes, as in the erythrocyte¹⁶. The membrane-bound activity in liver was near-maximal over a fairly broad range of pH (~5.0–7.2), also like the erythrocyte enzyme. The erythrocyte Ins(1,4,5)P₃ 5-phosphatase is very sensitive to inhibition by Ag⁺ and Zn²⁺ (ref. 16), but problems of solubility prevented the use of these ions in the iso-ionic media employed in our experiments with liver cell fractions. However, we have recently shown that the erythrocyte enzyme is very sensitive to inhibition by Cd²⁺ (C. E. King, unpublished data), and the membrane-bound Ins(1,4,5)P₃ phosphatase of liver is similarly inhibited by this ion (Fig. 2). The membrane-bound Ins(1,4,5)P₃ 5-phosphatase activity was insensitive to concentrations of Li⁺ up to 10 mM and was inhibited only by high concentrations of F⁻ (k_i ~3 mM). The smaller proportion of the Ins(1,4,5)P₃ phosphatase activity that was present in the soluble fraction was studied in less detail (because of the problems inherent in assaying Ins(1,4,5)P₃ hydrolysis without interference from further hydrolysis of the liberated Ins(1,4)P₂), but its general characteristics appeared similar to those of the particulate activity.

The soluble activity that hydrolysed Ins(1,4)P₂ yielded both a labelled inositol monophosphate and labelled P_i. Because the Ins(1,4)P₂ used as substrate was labelled only in the 4-phosphate, initial attack must have occurred at either phosphate group. The labelled Ins(4)P produced during these incubations was slowly dephosphorylated. Ins(1,4)P₂ hydrolysis was much less sensitive to Cd²⁺ inhibition than was hydrolysis of Ins(1,4,5)P₃ (Fig. 2); it was, however, sensitive to inhibition by Li⁺ (k_i ~2.5 mM) and F⁻ (k_i ~0.2 mM). The soluble activity responsible for Ins(1)P hydrolysis, like the Ins(1)P phosphatase of brain¹⁷ and other tissues¹⁹, was sensitive to inhibition by Li⁺ (k_i ~4 mM) and F⁻ (k_i ~0.2 mM).

These results, obtained using incubation conditions similar to those within the cytosol, indicate that the pathways that inactivate Ins(1,4,5)P₃ and return its inositol to the free inositol

pool of the cell are as shown below:

These results have several interesting implications. First, hydrolysis of Ins(1,4,5)P₃ involves the selective removal of its 5-phosphate by a phosphatase which appears to be localized, at least in part, at the plasma membrane. This enzyme will effectively terminate the mobilization of Ca²⁺ by Ins(1,4,5)P₃, as it yields Ins(1,4)P₂ which is essentially incapable of mobilizing Ca²⁺ from intracellular stores^{7–12}. From the relatively limited results obtained so far, it seems that the Ins(1,4,5)P₃ 5-phosphatase of liver is very similar to that of the erythrocyte both in its plasma membrane localization and its inhibition characteristics. The function of the Ins(1,4,5)P₃ 5-phosphatase activity of erythrocyte plasma membranes is unknown, but it might be a remnant of a hormonal signalling system which functioned during the haematopoietic stages of the cells' development¹⁶. This would be analogous to the retention of the guanyl nucleotide-dependent coupling proteins of the adenylate cyclase system in mature erythrocytes (for example ref. 20). The similarity between the membrane-bound Ins(1,4,5)P₃ 5-phosphatases of liver and erythrocytes provides some support for the notion that the experimentally accessible erythrocyte enzyme may be useful for investigating the characteristics of the enzymatic mechanism(s) by which Ins(1,4,5)P₃ is inactivated in stimulated cells.

Hydrolysis of Ins(1,4)P₂ and of both isomers of InsP is much slower than hydrolysis of Ins(1,4,5)P₃, as also observed with blowfly salivary gland¹⁵. Thus it seems likely that under normal circumstances the former reactions control the rate at which inositol derived from Ins(1,4,5)P₃ is returned to the cellular pool of free inositol. In the presence of Li⁺, these reactions are substantially inhibited, and inositol is trapped in the phosphates^{19,21}.

The hydrolysis of Ins(1,4)P₂ by soluble phosphatase activity does not show a precise positional selectivity like that of Ins(1,4,5)P₃: the 1- and 4-phosphate groups are removed at approximately similar rates, and the released Ins(1)P and Ins(4)P are both more slowly dephosphorylated by soluble phosphatase(s). The studies reported here do not show whether a single enzyme, which is sensitive to inhibition by Li⁺ and F⁻, is responsible for hydrolysis of Ins(1,4)P₂ and of the inositol monophosphates, or whether a different enzyme is involved in

Fig. 2 A comparison of the sensitivities to inhibition by Cd^{2+} of particle-bound $\text{Ins}(1,4,5)\text{P}_3$ 5-phosphatase (●), soluble $\text{Ins}(1,4)\text{P}_2$ phosphatase (○) and $\text{Ins}(1)\text{P}$ phosphatase (△) from rat liver. Enzyme activities were measured as described in Table 1, in the presence of various concentrations of Cd^{2+} . Results are the mean $\pm$ s.e.m. ($n \geq 4$). Values for s.e.m. $< 1\%$ have been omitted.

each reaction. Sherman and colleagues²¹ have recently identified small quantities of $\text{Ins}(4)\text{P}$ among the inositol phosphates that accumulate as a result of receptor activity in the brains of Li^+ -treated rats. It seems probable that this novel phosphate ester is produced from $\text{Ins}(1,4,5)\text{P}_3$, generated as a result of receptor activity, by the reactions shown in the scheme above.

An approximate extrapolation from the first-order rate constant given in Table 1 suggests that, in intact liver cells, the half life of $\text{Ins}(1,4,5)\text{P}_3$ is likely to be of the order of 4 s, suggesting considerably faster degradation of this compound than was reported in parotid fragments on termination of a stimulus^{13,14}. However, a recent report from Irvine and colleagues has shown that not only $\text{Ins}(1,4,5)\text{P}_3$, but also inositol 1,3,4-trisphosphate ($\text{Ins}(1,3,4)\text{P}_3$), accumulates in stimulated rat parotid fragments²², with the unexpected 1,3,4-isomer predominating. The reason only small quantities of $\text{Ins}(1,4,5)\text{P}_3$ were detected might be that this phosphate ester is degraded much more quickly than $\text{Ins}(1,3,4)\text{P}_3$; nothing is yet known about the pathway by which the latter compound is degraded.

We thank the MRC for project grant support and for a research studentship (to D.J.S.), and Eleanor Metcalf for her participation in the initial studies. We thank Alan Wallace for helpful advice on density gradient centrifugation.

A developmental gene product of *Bacillus subtilis* homologous to the sigma factor of *Escherichia coli*

Patrick Stragier*, Jean Bouvier*, Céline Bonamy† & Jekisiel Szulmajster†

* Institut de Microbiologie, Bâtiment 409, Université Paris-Sud, 91405 Orsay Cedex, France

† Laboratoire d'Enzymologie du CNRS, 91190 Gif-sur-Yvette, France

Sporulation of *Bacillus subtilis* involves sequential morphological and biochemical changes and is regulated by specific genes (*spo* genes) estimated to occupy more than 30 loci^{1,2}. A mutation in any one of these genes blocks the sporulation process at the corresponding developmental stage. Despite intensive genetic studies, the nature and function of the *spo* gene products remain unknown. Vegetative *B. subtilis* RNA polymerase core enzyme may interact with several sigma factors and discriminate among different classes of promoters³. During sporulation, new polypeptides are associated with the core enzyme which may have a central role in modifying its promoter recognition specificity^{3,4}. As a first step to understanding their function in the switch from vegetative to sporulation mode, several early sporulation genes have been cloned and analysed⁵⁻⁷. Here we report the cloning and nucleotide sequence of the *spoIIg* gene of *B. subtilis*^{8,9}. This gene encodes a polypeptide with a predicted relative molecular mass of 27,652 which contains a 65-amino acid region highly homologous to an internal part of the *Escherichia coli* sigma factor.

From a genomic library constructed as described previously¹⁰, but enriched in DNA restriction fragments of 2-6 kilobases (kb), we isolated a new recombinant plasmid that was able to transform to the *Spo*⁺ phenotype both *Rec*⁺ and *Rec*⁻ *spoIIg* recipients, indicating that the insert carried the entire *spoIIg* locus. The 3.6-kb insert was analysed by endonuclease restriction mapping (Fig. 1) and was further reduced by several subcloning steps. Ligation of a 1.1-kb *Pst*I fragment in the *Pst*I site of the pHV33 vector yielded plasmid pGSIIG11, still carrying the intact *spoIIg* locus, as shown by its transforming activity.

The 1,133-base pair (bp) nucleotide sequence of the pGSIIG11 insert (Fig. 2) was determined by the method of Maxam and Gilbert¹¹ according to the strategy outlined in Fig. 1. There is only one large open reading frame potentially encoding a polypeptide. As the requirements for translation initiation are more stringent in Gram-positive bacteria than in *E. coli*¹², a strong ribosome binding site is usually found in the vicinity of the translational start codon of *B. subtilis* genes. Such a sequence, AGAAGGGAG, appears at position 164 and precedes by six nucleotides an in-frame ATG codon. It seems probable that initiation of translation *in vivo* occurs at this codon, leading to the synthesis of a 239-amino acid polypeptide with a relative molecular mass (M_r) of 27,652. This polypeptide is rich in charged amino acids (33.5%) with an excess of basic residues over acidic ones (42 versus 38). These charged residues are not randomly distributed: the basic ones are clustered in the terminal

parts of the polypeptide (8 among the first 22 residues and 8 among the last 18 residues), while a stretch of 10 acidic residues is found in an internal region, between amino acids 135 and 163. These features may be significant for the biological activity of the *spoIIG* gene product.

The encoded protein seems to be synthesized in a very low amount as we have been unable to express it in *B. subtilis* maxicells in various experimental conditions; this suggests that the protein may have a regulatory role in sporulation. Note that the *spoIIG* gene is transcribed only in the early stages of sporulation and not during vegetative growth. This was demonstrated by hybridization experiments in which the gene was used to probe mRNAs isolated at different stages of growth and sporulation (results not shown).

To elucidate the nature of the polypeptide encoded by the *spoIIG* gene, we searched for homologies with known proteins stored in the Dayhoff protein sequence data bank (~2,300 sequences). An important homology was found with the product of the *E. coli rpoD*¹³ gene, the sigma factor. Figure 3a shows the alignments of the two related segments of the *B. subtilis spoIIG* gene product and of the *E. coli* sigma factor. These aligned sequences exhibit a remarkable similarity: of the 65 positions compared, 29 (44.6%) are occupied by identical amino acids. When chemically similar pairs of amino acids are taken into account¹⁴, this number rises to 44 (67.7%). It was not necessary to introduce gaps to maximize this homology. Furthermore, statistical tests^{15,16} show that the similarities between the aligned sequences are highly significant; the probability that such a similarity is fortuitous is $<10^{-9}$ (Fig. 3a).

Analysis of the corresponding nucleotide sequences also revealed a high degree of similarity at the DNA level (100 matches over 195 positions, that is 51.3%; see Fig. 3b). A striking feature of the similarities is their clustering into three blocks of 34, 35 and 30 bp, where 73.5%, 80% and 70% of the respective positions are occupied by identical nucleotides. As the codon usage is not the same in *E. coli* and in *B. subtilis* (as indicated, for example, by the respective usages of the *trpE* genes of these two organisms^{17,18}), such similarities strongly suggest that the two genes are evolutionarily related.

The regions shown in Fig. 3 correspond to different internal parts of the two proteins: residues 58–127 of the 239-amino acid polypeptide encoded by *spoIIG* and residues 375–439 of the *E. coli* sigma factor, a polypeptide of 613 amino acids¹³. However, their high degree of similarity strongly suggests a common function for these two protein domains. This leads to the attractive hypothesis that the *spoIIG* gene product may act as a specific sigma-like factor and that the region it has in common with the genuine *E. coli* sigma factor may similarly be involved in binding to the core RNA polymerase. This hypothesis is strengthened by the known functional and structural relationship between the *E. coli* and *B. subtilis* core RNA polymerases^{19–21}. Moreover, recent nucleotide sequence analysis of the *B. subtilis* σ^{55} structural gene (R. H. Doi, personal communication) indicates that the homologous region in the *E. coli* sigma factor and the *B. subtilis spoIIG* gene product is conserved in the major sigma factor of *B. subtilis*, σ^{55} , confirming previous immunological experiments²². One obvious possibility is that the *spoIIG* gene encodes σ^{29} , a polypeptide associated with RNA polymerase purified from *B. subtilis* sporulating cells and conferring on it new promoter recognition specificity²³. σ^{29} is a M_r 27,000–29,000 polypeptide^{4,23,24} and appears about 1 h after the onset of sporulation²³, the exact moment at which the temperature-sensitive period starts in strain 279.1, a strain mutated in the *spoIIG* gene⁸. However, sporulation involves the expression of multiple gene sets and could rely on the presence of several alternative sigma-like proteins. The *spoIIG* gene product could easily be one of these, as yet uncharacterized, transcriptional factors.

We thank Françoise de la Torre for technical assistance in cloning the *spoIIG* gene, Isabelle Giri for help with computer sequence analysis and Jocelyne Mauger for typing the manuscript. This work was supported by a CNRS grant (LA 136) to P.S. and J.B.

Note added in proof: The region of homology between the *B. subtilis spoIIG* gene product and the *E. coli* sigma factor has recently been found to be conserved also in the heat shock regulatory protein of *E. coli*²⁷.

BECAUSE of an editorial error, an incorrect figure was used in this letter. The correct Fig. 3 is shown below.

African marsupials— vicariance or dispersion?

UNTIL recently the marsupials were not recorded in Africa, but two recent discoveries in the Lower Eocene and in Lower Oligocene of North Africa have demonstrated the presence of this group of mammals on the continent. Their phylogeny and palaeobiogeography must, therefore, be reconstructed.

The discovery of marsupials in the Lower Oligocene of Africa has recently been interpreted as indicative of continuous land dispersion across the Tethys from Europe to Africa¹. Another recent discovery, however, proves that marsupials were present in northern Africa in the late Lower Eocene². The upper molar described from the north-west Sahara displays both primitive characters (the narrowness of the protocone) and very derived characters (dilambdodonty), which could suggest either immigration from a European centre of origin or survival of an ancestral stock common to South America and Africa before the opening of the South Atlantic (vicariance).

A vicariant origin for the African marsupials should not be excluded, because the time when the main marsupial dental characters appeared³, which would permit an evolutionary evaluation of African Oligocene and European late Eocene marsupials, is unknown. Unfortunately there is no way of testing the phyletic relationships between the Saharan and Egyptian forms, due to the scanty fossil record. On the other hand, European or Holarctic origin is supported by the continuous record of mammals of Holarctic affinities discovered in the Palaeocene⁴, Eocene^{5,6} and Oligocene⁶ of Africa, and by the absence of marsupials from the only known Palaeocene mammal fauna of Morocco⁴. The recent discovery of marsupials in the European Palaeocene⁷ reinforces this interpretation. However, several other palaeobiogeographic scenarios might also help to explain their presence in Africa. According to Sigé⁸, Africa could have been a land route between South America and North America, but there is no evidence of non-marsupial vertebrate dispersion to support this hypothesis.

Several authors have claimed that Africa could have been a link during early Cenozoic between South America and Europe for phorusrhacids⁹, mesosuchian ziphodont crocodiles¹⁰, characid fishes⁴ and marsupials⁷. As in the case of Africa, models which exclude Asia and the Indian plate need to be reconsidered. No true marsupial has been discovered in the Asian Mesozoic, but very few micromammals have been described from the rich mammalian assemblages of the Chinese early Tertiary. Additional information is provided by molecular data. For example, the structure and

sequence of neuropeptides¹¹ have recently shown that the most primitive living marsupials are Australian, thereby suggesting that Australia could have been the dispersion centre of the group. In conclusion, these new data demonstrate that the phylogeny and palaeobiogeography of marsupials is much more complicated than previously assumed, and should stimulate new research in many fields.

BOWN AND SIMONS REPLY—Jaeger and Martin suggest a possible vicariant origin for newly discovered marsupials from the Lower Eocene of Algeria and the Oligocene of Egypt^{1,2}. These are the only metatherian remains ever recovered from the African continent, and the vicariance hypothesis suggests that these animals are survivors of an ancestral marsupial stock common to South America and Africa before the opening of the South Atlantic (before the early Cretaceous³). The distributions of at least the early Tertiary marsupials of Europe and North America might then have been derived from this remnant African stock, rather than having originated in Europe, as we have claimed² for the Egyptian marsupial, or in North America, as suggested by others^{4,5} for the Euramerican marsupials. Although a vicariance theory of origin of mammalian groups is in vogue, its application to this problem and to others is generally supported only by negative evidence, that is, the absence of a good fossil record. For African marsupials, a vicariant origin is the least parsimonious alternative and requires detailed speculation about the composition of a non-existent fossil record.

First, there are no known pre-late Cretaceous marsupials from South America (the late Cretaceous marsupials from Peru are virtually identical to North American late Cretaceous *Alphadon*⁶). Second, the only proposed marsupial of early Cretaceous antiquity from anywhere in the world is North American *Holo-*

*clemensia texana*⁷, a form that some feel is of doubtful metatherian affinity^{8–10}. Even if *Holoclemensia* is metatherian, vicariance biogeography would place the origin of the Metatheria in North America, in accordance with most current thought. Third, the combination of primitive and derived characters in the Eocene Algerian form is unknown in any other didelphid, including those from South America, and the Egyptian marsupial shares derived characters with late Eocene and early Oligocene marsupials from Europe. By a vicariant origin, the Didelphidae of South America and those of Euramerica would have to be polyphyletic, or else the South America didelphids were at some time reintroduced there from Africa via Euramerica. Fourth, Egyptian *Peratherium* is so like European species of the genus, that had the Old World didelphids originated in Africa and spread to Euramerica, the avenue of dispersal between Africa and Europe must have been irregularly maintained over many millions of years. The first three points are not supported by palaeontological evidence, and the last observation is directly opposed to what is known of Tethyan palaeogeography during the early Tertiary.

Although Jaeger and Martin are correct in observing that a vicariance origin for the African marsupials should be examined, there is no evidence to support their hypothesis involving the composition and dispersion of an unknown fauna. We believe that there is some evidence that the Egyptian marsupial was an early Tertiary immigrant from Europe. Marsupials were probably present in Europe during the Palaeocene¹¹, although they are as yet unknown from mammalian microfossils of that age in Africa. The Egyptian marsupial cannot have arrived in Egypt before the latest Eocene because of marine conditions there. Its appearance in the Egyptian continental Oligocene approximately coincides with the Tethyan regression, when Europe and Africa were presumably separated by less water distance than for many millions of years previously.

We also observe that the presence of a single stylar cusp on a narrow stylar shelf, in conjunction with the more or less dilambdodont molar structure in the specimen from the Eocene of Algeria, is so unusual for a marsupial as seriously to jeopardize its assignment to the Metatheria. The tooth appears to share at least as many derived characters with European *Remiculus* (Mixodectidae) and *Adapisoriculus* (Insectivora, *incertae sedis*) as it does with any marsupial.

Finally, we did not "... interpret the discovery of marsupials in the Lower Oligocene of Africa as indicative of continuous land dispersion across the Tethys from Europe to Africa", as Jaeger and Martin suggest. Rather, we observed that the palaeogeographical reconstructions do

not favour a direct land connection of Africa with Europe at that time².

Cometary showers and unseen solar companions

THE existence of an unseen solar companion has occasionally been invoked to account for some unsolved astrophysical problem. The latest hypothesis, as proposed by Whitmire and Jackson¹ and by Davis *et al.*², is that such a companion, in a distant eccentric orbit, periodically passes through the Oort cometary cloud and causes a shower of comets from an also unseen inner Oort cloud reservoir. Impacts on the Earth from these repeated showers then results in periodic biological extinction events.

A shower of comets from the inner Oort cloud is expected to involve some 2×10^9 comets passing four times each within the orbit of the Earth, over a period of $\sim 10^6$ yr. This episodic flux is equivalent to the presently estimated steady-state cometary flux of 16 comets $\text{AU}^{-1} \text{yr}^{-1}$ (ref. 3) (brighter than $H_{10} = 11$) for a period of 500 Myr. Thus, the seven to nine cometary showers, spaced at 28-Myr intervals, for which a cratering record has allegedly been found⁴, would produce as many craters as the steady-state cometary flux over the Solar System's entire history.

Present estimates of the cratering rates on the Earth and Moon based on dated surfaces of very different ages⁵, are in agreement with one another, after allowing for differences in gravity-scaling and impact cross-section. Estimates of the expected cratering from Earth-crossing asteroids are roughly twice these values⁶; estimates of the cratering from comets range between 0.3 and 1.0 times the rate based on dated crater surfaces^{7,8}. Although it seems that the known Earth-crossing objects yield a total cratering rate on the Earth and Moon which is too high, the problem is not serious because of the large error bars in these calculations.

However, adding the flux predicted for cometary showers every 28 Myr makes the problem significantly worse. These showers result in an 18-fold increase in the mean cometary flux over the past 400 Myr, resulting in between 5.4 and 18 times as many additional craters on the Earth and Moon in that period, outside any reasonable error limits on these rates.

Even allowing this discrepancy, the probability that such a cometary shower would result in the impact of a 10-km diameter cometary nucleus on the Earth is about 0.055 per shower. Thus, major events like the Cretaceous-Tertiary (K-T) extinction might be expected on average every 510 Myr, considerably longer than is observed.

One can also consider the stability of the hypothesized 'death star' orbit. With a perihelion of 3×10^4 AU and a period of 28 Myr, the proposed companion star would have an aphelion of 1.54×10^5 AU. Monte Carlo simulation modelling of the dynamical evolution of a large sample of hypothetical stars starting with that orbit⁹ has shown that 23% escape the Solar System in 10 orbits or less, and 86% escape in $< 10^9$ yr. The average change in orbital period per orbit is 10%. Thus, it is unlikely that an unseen companion star could have remained in a constant period orbit, over the period suggested by the terrestrial extinction record, and impossible that it has been in that orbit since the origin of the Solar System.

If a more tightly bound original orbit were to be assumed, the problem of the increase in the terrestrial cratering record would only worsen because of the increased frequency of cometary showers implied. Also, the Oort cloud population would have been severely depleted by the repeated perturbations of the companion star, implying an immense initial cloud mass. If, on the other hand, one assumed that the companion star had been recently captured, an event with a probability of 10^{-13} , we would still expect an approximate doubling of the cometary cratering on the Earth in the past 300 Myr.

Finally, an additional problem with the death star scenario is that there do not seem to be many random events mixed with the periodic signal from cometary showers. Random Apollo asteroid impacts should produce a major extinction every 10^8 yr or so, and large (though not necessarily catastrophic) cometary impacts should occur with about one-third that frequency.

The proposed death star scenario, however interesting, has consequences which its proposers have failed to consider, and for which we have little evidence. If the periodicity in the fossil extinction record is indeed real, then some other mechanism must be found for creating it. It would seem wise to look for a period of which we are already aware, for example, the time between the Sun's galactic plane crossings is close to the required

value, though the extinction mechanism remains a mystery. Even so, this would seem a more worthwhile avenue for future study than continuing to chase an invisible star which does not exist.

MULLER *ET AL.* REPLY—Weissman's objections are based, we believe, on a misunderstanding of the companion star model^{1,2} and a misinterpretation of the periodicity discovered in the crater data³. We will review the salient features of these before addressing Weissman's points directly.

In the companion star model, the Sun's companion has an orbit with a 26-Myr period, matching that seen in the mass extinctions⁴. During perihelion, it passes close enough to the Oort cloud of comets to precipitate a shower in the normally depleted 'loss cone' region swept clean by Jupiter and Saturn; this requires the companion's orbit to have an eccentricity greater than ~ 0.6 . The number of comets in the shower depends on the number in the inner part of the Oort cloud, but this number is not known within a factor of 10. If we take the nominal value of 10^{13} from the extrapolation of Hills⁵, we find the number of comets in a shower to be 2×10^9 and the number of impacts per shower to be 25; but these numbers could be as small as 4×10^8 and 5, respectively.

As stated in our original paper¹, and subsequently checked with detailed calculations⁶, the orbit we postulate is stable, with a half life of $\sim 10^9$ yr, not long enough for the companion star to have been in such a large orbit at the formation of the Solar System. As it is extremely unlikely that a star could have been captured by the Sun, the most likely scenario has the companion in a relatively tight orbit 5×10^3 yr ago, with perturbations from passing stars and molecular clouds over 5×10^9 yr expanding the orbit to the present one.

In Grieve's survey of impact craters on the Earth⁷, there are 58 craters with ages < 250 Myr, but only 29 of these have uncertainties in their ages of 20 Myr or less, and only 13 of these remain when we exclude the very recent (< 5 Myr old) craters; these appear in a table in our paper³. Our analysis of these craters showed a statistically significant periodicity, with period and phase identical

(within errors) to those found in the fossil record. On closer examination we found that most of the signal was coming from the 11 largest craters, those with a diameter >10 km. One would expect comets in a shower to be larger than the background comets if, for example, the comets from the inner cloud were more massive than those from the outer regions, as might be expected from an accretion model of comet formation. Of the 11 large craters, one is clearly not associated with the periodicity, and as many as two others may be chance coincidences. Thus, the evidence indicates that about 9 ± 3 of the 13 craters with precise ages originated from the periodic showers. (The uncertainty estimate includes both systematic and Poisson errors.) Stated another way, we conclude that $70 \pm 25\%$ of the craters were formed during showers.

Weissman claims that the total number of comets hitting the Earth from showers is substantially greater than the number hitting in the time between showers—this is not necessarily true in our model, and the impact data indicate that the numbers may be roughly equal. Perhaps Weissman's confusion comes from a poorly worded statement in our original paper¹ that the number of comets that arrive in a single shower "may be as much as one or two orders of magnitude greater than the number that arrive between showers". In this statement we were referring to the effects of the companion star alone, and were not including comets whose infall is triggered by random passing stars. Weissman states near the end of his letter: "there do not appear to be many random events mixed with the periodic signal"; as stated above, we believe that $30 \pm 25\%$ of the impact craters (principally those with diameters <10 km) may be random in arrival times.

Weissman says that the probability of a large comet (with a 10 km nucleus) hitting is small, and that such impacts are likely to occur every 500 Myr, a period "considerably longer than is observed". Only one such large impact has been proven in the last 250 Myr—the one at the end of the Cretaceous. The crater for this impact, if it still exists, should be 100–200 km across. (If the crater is on the sea floor it would not have been found.) All the other extinctions during this period were smaller, with associated craters 10–100 km across. Weissman claims there should be one large impact in 500 Myr; the data show one in 250 Myr. Although we do not necessarily accept Weissman's number (he does not give a derivation) we find no significant discrepancy with the data.

If the orbit of the companion star were once much closer to the Sun, as is necessary in our model, then Weissman objects that the showers would have been more intense in the past. This is true, but is not an objection. In fact, there is clear evidence that bombardment in the remote past was once much greater than in the

last 250 Myr. The 'late heavy bombardment' of the Moon (when most of the lunar craters were formed) ended 3.9×10^9 yr ago, conceivably when the companion star was scattered to a larger orbit. Weissman correctly states that an ancient close-in orbit would have severely depleted the Oort comet cloud, implying that there was originally an 'immense cloud mass'. As the mass of this early cloud could still have been much less than the mass of the companion star, we can see no valid objection. If the companion star exists, then we certainly will have to change our models of the dynamics of the early Solar System. But inconsistency with the models is not the same as inconsistency with the data on which those models were based. We know of no data inconsistent with our model of a solar companion star, and we know of no alternative model consistent with the measured period and phase of the impacts.

WHITMIRE AND JACKSON REPLY—The contribution of shower comets to the mean cratering rate need only be comparable to the (assumed) steady-state random contribution to produce a strong signal in the Fourier spectrum of dated craters. The number of terrestrial impacts resulting from a shower of 2×10^9 comets, brighter than $H_{10} = 11$ and with perihelia ≤ 1 AU, is given by the product of (2×10^9 comets) and (4 perihelia passages per comet) and (2×10^{-9} impacts per perihelion passage), which is equal to 16 impacts. According to Weissman¹, a long period comet, brighter than $H_{10} = 11$, has a mass $\geq 5 \times 10^{14}$ g and produces a crater ≥ 20 km in diameter. The mean cratering rate, for craters ≥ 20 km, over the last 300 Myr is² $0.35 (\pm 0.13) \times 10^{-14} \text{ km}^{-2} \text{ yr}^{-1}$, which corresponds to ~ 50 impacts of comets, brighter than $H_{10} = 11$, per 28 Myr. Thus the shower contribution to the mean cratering rate is less than the total rate and comparable to the mean background rate.

According to Wetherill and Shoemaker³, a random 10-km asteroid is

expected to impact on the Earth about every 50 Myr. The absence of any random extinction events⁴, and the evidence that major extinctions occur over intervals of ~ 1 Myr, both suggest that the primary extinction mechanism may be associated with the enhanced impact rate (≥ 30 times background) during a shower, rather than with a single catastrophic impact, although such an event should also occur occasionally.

The stability of the companion's present orbit towards stellar perturbations and the galactic tides has recently been investigated by Hut⁵ and Hills⁶. These results indicate that the orbital period should random-walk away by 10–20% over a 250-Myr interval, a result not obviously incompatible with the cratering and extinction data. The evolution of the companion from a tighter orbit⁷, and the associated cratering rates, remain to be investigated in detail.

Sepkoski and Raup⁴ have recently extended their original analysis and have further restricted the uncertainty in the extinction period. They find the period to be 26.2 ± 1 Myr and conclude that this is incompatible with the 33 ± 3 -Myr interval between the Sun's galactic plane crossings.

The maximum entropy method for data analysis

IN data analysis it is very satisfying when a useful technique, which has arisen in a more or less *ad hoc* manner, finds respectability as a manifestation of some formal theory. Skilling¹ invokes this argument for using the maximum entropy method for data analysis. Experience that the procedure often seems to work quite well is strengthened by reference to recent theoretical work. Skilling's conclusion is that maximum entropy is the only regularization method that should be used for a very wide range of data analysis. I suggest that this claim is unjustified on both pragmatic and theoretical grounds.

Let us confine our attention to one specific application, the enhancement of images as illustrated in Fig. 1 of Skilling's paper. What seems to me the major advantage of the maximum entropy method over many, but not all, other regularization

procedures, is the practical one that the resulting image, in being non-negative, automatically represents a valid solution. This results from the presence of $\log p_i$ in the formula for entropy. With other procedures, the values obtained for some p_i might be unrealistically negative. Even then, however, the complete solution could well be quite adequate in many applications and could well be attained with comparatively little computation.

In most applications of regularization, the regularization functional, exemplified in this method by entropy, S , incorporates some prior belief about the local smoothness of the true image. For example, suppose the pixels are ordered so that p_i and p_j are likely to be similar if i and j are close together; then one might consider, as an alternative to S , a criterion such as $-\sum(\log p_i - \log p_{i+1})^2$. At a higher level, one will know, *a priori*, that Fig. 1 is a smudged photograph of a car. The entropy functional does not permit representation of spatial ideas of this type. Certainly the cross entropy $S = -\sum p_i \log(p_i/m_i)$ allows for some acknowledgement of a prior model m but leaves the question of how to obtain m in any given application. There is the *ad hoc* suggestion of using the data to produce a preliminary m , but this would require using the data twice, first to find m and then to carry out the regularization. This is pragmatically reasonable, if not inevitable, but cannot be regarded as being formally respectable.

My principal point, however, is to dispute the main thrust of Skilling's article, that the maximum entropy method for data analysis, as used in the production of Fig. 1, stands in splendid isolation, on fundamental grounds. This statement is based on the axiomatic work of Shore and Johnson² and of Tikochinsky *et al.*³. They show that the choice of a probability distribution required to fit certain linear constraints has to be made on the basis of maximum entropy if certain axioms have to be satisfied. Typically, the effective constraints in the image-processing problems are highly nonlinear, and are expressed by the intensities themselves, not their proportions. It is not obvious that the mathematics of Shore and Johnson carry over to such a problem, and I cannot accept that their axioms, particularly those of subclass and system independence, are relevant to the regularization context. Tikochinsky *et al.*, in their discussion of reproducible experiments, specifically require the p_i to be probabilities; the assumption of linear constraints is vital, and even their definition of reproducible experiments does not correspond with the interpretation given by Skilling.

Thus, the maximum entropy method for data analysis is a useful tool, with some practical advantages and disadvantages over other regularization procedures. It is mildly interesting that there are links with the formal work on the principle of maximum entropy but the parallel simply

has not been shown to be exact enough to disallow flexibility in choosing a procedure to clarify Fig. 1 of ref. 1. As 'consistency', as defined by Shore and Johnson, seems irrelevant in this context, we need not fear the charge of inconsistency by rejecting entropy.

D. M. TITTERINGTON

SKILLING REPLIES—I find the arguments for using maximum entropy to be deeply compelling. In fact, I am unable to improve on Titterington's own words: "the maximum entropy method ... stands in splendid isolation, on fundamental grounds". Quite so. However, he takes me to task for not going beyond the description of an image as a set of probabilities/proportions to incorporate "some prior belief about the local smoothness of the true image". In this he has raised a most important point: clearly, the simple entropy formula $S = -\sum_i p_i \log(p_i/m_i)$ does not include any such belief; just as clearly, maximum entropy is losing power by ignoring this, provided of course that it is realistic to expect smoothness, or spikiness, or cars, or whatever in one's images.

I hold that these more complicated situations should ideally be handled by extending a technique which is basically correct rather than by invoking *ad hoc* alternatives. As Titterington's preference for smoothness tends to zero, I would like his formulae to reduce to the simple entropy form which is the compelling solution to that problem. This is because the regularization function, which expresses my preference for different shapes of image, should be independent of the particular form of the data to be measured. Logically, my preferences precede the data, so that I should use the same function whether I have convolution data (as in the car example) or marginal data (as in the theoretical discussion).

Fortunately, maximum entropy can include such preferences in an easy and natural way. The trick is to develop the identification of p with the image. The simplest identification is to let i be a single index ranging over the cells of the image, and p_i the corresponding proportion of flux. However, we can also let i be a composite index ranging over pairs of cells, and p_i the corresponding product of fluxes (itself a proportion). The model m_i can now incorporate pair correlations between cells as well as simple position-dependent information. If we take i to be a highly composite index, the model can encode correspondingly subtle details of prior knowledge. The arguments for using maximum entropy still hold, and we have been exploring this development. True, I

do not (yet?) know how to encode 'smoothness' in an absolute as opposed to *ad hoc* fashion. Nevertheless, I hope I have answered constructively Titterington's first major comment.

Concerning the relevance of Shore and Johnson's axioms¹, I do not think that the distinction between linear and nonlinear constraints is important here. The form of the experimental constraints is quite separate from the form of one's prior belief about the observed image, as coded in the regularization formula. Shore and Johnson explicitly state that their mathematics include nonlinear constraints. They use the technical trick of replacing a (convex) nonlinear constraint by that set of linear inequality constraints which defines the hull of the nonlinear constraint. Tikochinsky *et al.*² do not state this, having had physical applications in mind, but clearly the same trick can be used.

If the experimental constraints include dimensional information on intensities, the maximum entropy image will be accompanied by a dimensional number describing its normalization. Defining the regularization in terms of proportions rather than intensities merely requires the resulting image to have the same shape whether the data refer to microwatts or megawatts. The point about the subclass and system independence axioms is not that they hold for an arbitrary collection of data (such as a blurred photograph), but that they are compelling for particular collections (such as marginals). If one particular type of data forces me to use entropy, then I will consistently use entropy for other types also.
